Power rating. Highest efficiency and best power factor are obtained by operating a motor continuously at as near its rated capacity as possible. Hence motors for driving stamp batteries, ball, rod or pebble mills, compressors or blowers, pumps, and other steady-load apparatus, should have capacities corresponding as closely as practicable with the power requirements. For driving coarse crushers, rolls, Chilean mills, tables, agitators or settling tanks, elevators, conveyors, and other equipment subject to irregularity in feed or to excessive and variable friction, a motor should have a capacity two or three times greater than the normal requirement. The bad effect of so many oversized motors on the power factor of a whole mill is not unduly serious, because in most mills, particularly those compelled to crush fine, a large part (50 to 75 per cent.) of the total mill power is applied to the driving of steady-load equipment by efficient motors.

Table 25. Distances of transmission

Distances to which 100-kw. three-phase current can be transmitted over different sizes of wires at different potentials, assuming an energy loss of 10 per cent. and a power factor of 85 per cent.

Number B. & S.	Area in circular mils	Voltages 2,000	3,000	4,000	5,000	6,000	8,000
		Distance of transmission in miles for various potentials at receiving end					
6	26,250	1.32	2.98	5.28	8.27	11.9	21.1

Table 27. Speed of synchronous motors

Horsepower rating	Speeds, revolutions per minute	
	Belts	Gears(*a*)
1–2	1800	900
5	1200	900
7½–10	1200	720
15	1200	600
20–50	900	600
75–100	720	514
150–200	600	450

a Plain spur gears; with herring bone gear, chain drive, or a flexible coupling on motor-shaft extension, the same speed may be used as recommended for belts.

Table 28. Speed of general industrial motors

Speeds, revolutions per minute	Maximum horsepower of motor	
	Belted	Geared, steel pinions
1700 or 1800	40	5
1440 or 1500	50	10
1150 or 1200	75	25
850 or 900	125	50
720 or 750	....	75

Applicability of motor types (*115 J 1147, 109 J 849, 118 P 819, Peele; E Bachman, PC*). The special fields for the various types of motors are given below; direct-current motors are included in view of their occasional desirability:

DIRECT-CURRENT MOTORS

Shunt-wound

When the work is of a fairly steady nature.
When a considerable range of speed adjustment is desired.
When fairly close speed regulation is required.

Compound-wound

When there are sudden heavy loads of short duration.
When heavy starting duty is required.
Where, for these duties, series motors could not be used on account of excessive light-load speeds.

Series

When excessive starting torques are required, but only when speed regulation is not important and when light-load speeds do not become dangerous.

ALTERNATING-CURRENT MOTORS

Squirrel-cage

For constant speed with normal starting duty.

Squirrel-cage with high-resistance rotors

For constant speed and heavy starting duty or when heavy loads of short duration are expected.

Double squirrel-cage

For excessive starting duty when the running duty would require a standard constant-speed squirrel-cage motor. Simplifies control.

Slip-ring

For heavy duty when some speed adjustment is necessary. These motors have the characteristics, not of d-c. adjustable-speed motors, but of d-c. motors with armature control, the current consumed in the resistance to reduce speed being wasted.

Multi-speed

When direct current is not available and three or four definite speeds, in conjunction with gear changes, will give the desired speeds.

Synchronous

When load can be started by clutch or when the starting load is light. Applicable to centrifugal pumps starting under no load, and to air compressors or blowers where the load is increased after full speed is reached.

Super-synchronous or "Built-in Clutch" type synchronous

When the load requires high starting duty but low and constant speed; ball and tube mills are typical examples.

"Squirrel-cage" synchronous

When the normal starting duty is too great for a standard synchronous motor, *e.g.*, automatically-started compressors, pumps, etc.

The distinguishing features of the three simple types of alternating-current motors compare as follows:

SYNCHRONOUS	SQUIRREL-CAGE INDUCTION	SLIP-RING INDUCTION
Constant speed.	Constant speed, fixed by frequency of the supply current.	Variable speed, usually by induction of resistance in the secondary circuit.
Adaptable to high voltages, thereby often obviating transformers.	Adaptable to high voltages.	Adaptable to high voltages.
Good efficiency and high power factor at all loads.	Good efficiency. Power factor lower than synchronous motor, especially at fractional loads.	Lower efficiency than squirrel-cage.
Power factor under control. Can be used to equalize poor power-factor caused by induction motors.	A low power-factor does not materially increase the power cost for driving the motor, but introduces greater voltage loss in the whole system, involving larger transformers, wiring, etc.	
Low starting torque (except with special design).	Good starting torque except with low frequency.	High starting torque.
Requires d-c. excitation.	Large current at start.	Small current at start.
Has collector rings.	No moving contacts.	Moving contacts may suffer from dust or moisture.
Skillful manipulation required at starting.	Easily started.	Easily started.
Costs more than induction motor.	Relatively cheap.	Relatively expensive.
	Principal uses	
Compressors or blowers.	Coarse crushers.	Intermittent hoist service.
Centrifugal pumps.	Rolls.	Variable-speed drives. Starting under heavy load, as elevators, plunger pumps, tube-mills without friction clutches, agitators and settlers.
Tube mills, if provided with friction clutches. Stamp batteries.	Groups of any equipment that can be started under small load.	
In general, for loads that can be added gradually.		

At United Comstock, operating at 440 volts exclusively (stepped from 60,000 and 2300 volts), the tube mills are driven by slip-ring motors with reversible controllers; more than ninety other motors in the plant (some of 200-hp.) are of squirrel-cage type, with automatic compensators and push-button starters (*114 J 846*, *117 J 516*). At Honduras Rosario, mainly on 2200-volts, 20 stamps are driven by a 200-hp. synchronous motor with belted exciter, started by a 35-hp. induction motor and automatic synchronizer; three tube-mills each have a 75-hp. slip-ring motor with flexible coupling and reversing starter (no clutch); all plunger pumps have slip-ring motors; the agitator compressor has a 75-hp. squirrel-cage motor. At Panda six synchronous motors (three of 350 and three of 525 hp., each at 6600 volts) are used to drive 2-stage centrifugal pumps for water supply of 10,000 gal. per min. against a head of 500 ft. (*29 MM 137*). The Alaska-Juneau mill contained several unusual features, made possible by an abundant supply of power from its own generators and those of the adjoining Alaska-Treadwell mine (*120 P 251*). Each of the two coarse-crushing sections contained one 36 × 48-in. jaw crusher and two No. 9 gyratories; these three crushers were driven by clutch pulleys on one shaft direct-connected to a 350-hp. synchronous motor of 2200 volts and 360 r.p.m., with direct-connected exciter. The starting torque was sufficient to start all connected equipment without releasing the clutches. The slow speed of this motor obviated countershafts and other reducers, space for which was wanting. Fine crushing, in two stages, was done in twelve ball mills (8 × 6-ft.) each driven by one 225-hp. motor, and twelve tube mills (6 × 12-ft.) each with one 150-hp. motor; all of these motors were of squirrel-cage type, 2200-volt, 435-r.p.m., specially designed for large starting torque. The mills had friction clutches, but it was

seldom necessary to use them; motors were thrown directly on the full line voltage by special circuit breakers and without compensators, but extra-heavy feeder lines were installed. The unbalancing caused by these motors was compensated by the synchronous motors at the coarse crushers. Two centrifugal pumps for mill water, 3000 gal. per min. each, were each driven by a 400-hp., direct-connected, squirrel-cage motor, not specially designed for high starting torque; a synchronous torque 33 per cent. of the full-load torque proved satisfactory. These motors were excited by independent d-c. circuit. At the SANTA BARBARA mill (*112 J 1050*), with nineteen motors aggregating 590 hp., three slip-ring motors of 100 hp. each are used for coarse crushing and rod-mill grinding, but all others are of the squirrel-cage type.

Mechanical transmission in some form is necessary between the motor and the driven machine.

Long belts are efficient, but may occupy space needed for other purposes. The belt span should not be less than five times the diameter of the larger pulley, and the more nearly horizontal the better; inclinations up to 60° are allowable.

Short belt, with a tightening idler permits the motor to be placed at either side or above or below the driven pulley, with a clear distance as small as 2 or 3 ft. between faces of pulleys; endless belt is practically unavoidable.

Chain drive is as efficient mechanically as a short belt with tightener and has the advantage of producing less journal friction in both sprocket shafts. The shaft must be accurately aligned and so mounted that the chain may be tightened. Wherever possible, vertical chain drives should be avoided and the machines should be mounted so that the chain may be conveniently taken off and replaced without undue loss of time. For this reason the sprockets should not be too close to walls or other machines.

Spur gearing is an accepted method of driving tube mills. Owing to the impossibility of preventing some longitudinal motion in the mill which will be transmitted to the pinion shaft, a motor cannot safely be rigidly connected to the shaft, but must drive through a flexible coupling; or by belt or chain, if further reduction of speed is desired. A further purpose of flexible couplings is to avoid minutely accurate alignment of the motor. A spur gear is often applied to an elevator drive, in which case the reduction should be made near the motor, the elevator being driven by belt from a jack-shaft. Geared machines must be accurately aligned and rigidly fastened to a common base. An error of a few thousandths of an inch may produce serious vibration and ultimately break the shaft or wreck the apparatus. When gears are properly meshed, it should be possible to pull a thin piece of paper from between the teeth without tearing.

Herringbone gear is more expensive than spur gears, but permits larger speed reduction and is sufficiently more efficient in power transmission to pay for itself easily in tube- and ball-mill drives where the motor is direct-connected to the pinion shaft.

Worm gear with high ratio of speed reduction is applied to such slow-moving apparatus as thickening tanks, and with a lower reduction ratio, in head motions of unit-driven tables and for conveyors. For driving inclined conveyors and all forms of bucket elevators, worm-gear drive avoids the necessity of safety devices to prevent back travel on stopping.

Bevel gears are found chiefly in gyratories, Huntington and Chilean mills, trommels, and M.S. flotation cells; they are usually a source of annoyance, and are to be avoided wherever possible.

Direct connection is desirable for high-speed and constant-speed apparatus, such as centrifugal pumps of moderate size, fans, blowers, etc., and even for slower-speed equipment, the advantages of direct drive may sometimes justify the additional expense of a slow-speed motor. Direct-connected machines must be mounted on and rigidly fastened to a common base in order to maintain accurate alignment and flexible couplings must be used to prevent trouble from end thrust. Couplings should be aligned with a straight edge placed against the outer diameter at top, bottom, and sides, with the rotating parts standing in different positions.

Electrical power transmission. (*E. Bachman, PC.*) The relation between kv-a., power, current, potential, and power factor in the different types of circuits is as follows:

Direct current. See **Fig.** *8a*. I = current per wire, in amperes; E = potential between wires, in volts; $P = EI/1000$ in kw.

Alternating current, single phase. See Fig. 8*b*. $\cos \phi$ = power-factor. Apparent power = Kv-a. = $EI/1000$ and $P = EI \cos \phi/1000$ in kw.

Alternating-current, 3-phase, 3-wire. See Fig. 8*c*. This is the most common form in which alternating-current energy for power purposes is produced. Potential to neutral, in volts = $e = E/\sqrt{3}$. Apparent power = Kv-a. = $\sqrt{3}\,EI/1000 = 3\,eI/1000$; and $P = \sqrt{3}\,EI \cos \phi/1000 = 3\,eI \cos \phi/1000$ in kw.

Alternating-current, 3-phase, 4-wire. A 3-phase, 4-wire system is commonly used in cases where it is desired to supply power at maximum potential to a number of single-phase independent circuits, which may and probably will be unbalanced; and at the same time have maximum assurance against insulation breakdown. For example, a 4000-volt Y-connected generator with the neutral grounded and brought out to form the fourth wire of a 3-phase, 4-wire system, may be used to supply power to single-phase transformers having 2300-volt primary windings and connected between one of the phase wires and the neutral. It is advisable to endeavor to balance this type of single-phase load so as not to overload any one phase of the generator while other phases remain underloaded. For a balanced load (equal load between each conductor and neutral) no current will flow through the neutral and the circuit may be considered simply as 3-phase, 3-wire. In case of an unbalanced load, the unbalanced current will flow through the neutral.

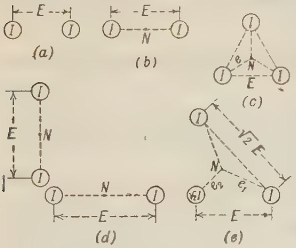

FIG. 8.—Power circuits.

Alternating-current, 2-phase, 4-wire. See Fig. 8*d*. Potential to neutral, in volts = $e = E/2$. Apparent power = Kv-a. = $2\,EI/1000$; $P = 2\,EI \cos \phi/1000$ in kw.

Alternating-current, 2-phase, 3-wire. I = current in outside wire, in amperes; $2I$ = current in common wire, in amperes; E = potential between outside and common wire, volts; $e_1 = 0.745\,E$ = potential between outside wire and neutral; $e_2 = 0.471\,E$ = potential between common wire and neutral. Apparent power = Kv-a. = $2\,EI/1000$; $P = 2\,EI \cos \phi/1000$ in kw.

Conductors are of the following classes: (*a*) Exposed bare conductors for ground connections. (*b*) Exposed insulated conductors mounted on insulators, for low and medium potentials. (*c*) Exposed bare conductors mounted on insulators, for high potentials. (*d*) Small insulated conductors in iron conduit. (*e*) Large insulated conductors in fiber or tile duct.

Short-circuit currents and their effects. An installation must be constructed proof against any reasonably conceivable abnormal condition. The most important, and possibly most frequent, cause of trouble is short-circuiting, despite most elaborate precautions. Hence all measures within reasonable expense should be employed to limit the destructive effects. The initial short circuit usually results from failure of insulation. Any circuit or piece of apparatus subject to short circuits should be removed from service as soon after the short circuit has occurred as is reasonably possible.

Four important provisions against short-circuiting must always be made: (*a*) Material of fireproof or fire-resisting nature should be used whenever possible; if not possible, apparatus and conductors should be segregated and enclosed by suitable barriers or cells, so that a fire resulting from a short circuit will be confined to a small part of the installation. (*b*) All apparatus and material should have ample strength to resist the mechanical stresses resulting from the abnormal flow of current during a short circuit. (*c*) All circuit breakers that may be called upon to open a short circuit should have ample capacity to rupture the maximum current that can flow at the instant they are called upon to operate. It is necessary not only that breakers be amply insulated to operate safely at the installation potential, and that the contacts have sufficient area to carry the maximum current during normal operation; but it is also necessary to know the maximum short-circuit current that they may be required to open and to be certain that each breaker selected has ample rupturing capacity to open that circuit safely. This is one of the most important points to be considered but unfortunately is the one most frequently neglected, often with disastrous results. (*d*) Current should not be allowed to flow through a short circuit any longer than can be avoided.

Bare conductors are usually employed when the voltage exceeds 15,000. These consist of solid wire, copper tubing, or iron pipe. The use of tubing makes it possible to reduce the number of expensive insulators used for sup-

port. It is expensive and quite unnecessary to insulate such high-voltage conductors because when properly installed they are widely spaced and kept well away from the ground.

Cable is used for inter-connection of apparatus and generally for low-voltage distribution. That for inter-connection should be of the best grade of material and installed in the best possible manner. The cost is but a small percentage of the total. Transmission cables may represent a considerable part of the total investment in electrical equipment when used for distribution of power to a number of isolated loads.

When large cables are multiplied to carry the current for low-voltage machines it is necessary to arrange and group the phases so that each conductor will have about the same reactance and thus the current will be properly apportioned between the different conductors in parallel. When dealing with large conductors, special care should be taken to support them rigidly so that they will not be torn from their supports should a severe short circuit occur.

Exposed cable runs. The best arrangement, provided the number of cables in close proximity does not make the group too congested or hazardous, is to use wires or cable insulated for full potential and rigidly supported on insulators good for full potential. This arrangement is safe, since each method of insulation affords full protection. Exposed runs are under constant observation. VARNISHED CAMBRIC is the most lasting insulation because it does not absorb moisture, like paper insulation, and does not deteriorate as rapidly as rubber. It should be thoroughly covered with a fireproof braid or tape to minimize communication between circuits in the event of a short circuit or ground on one circuit or conductor. A 3/32-in. asbestos tape with a flame-proof braid covering gives excellent fire protection.

Cables in conduits or ducts should be stranded. Iron conduit is ordinarily used up to 4-in. diameter; above this size fiber or tile is satisfactory and less expensive. Iron should not be used with alternating current unless all conductors of the circuit are in the same conduit. Rubber-covered standard conductors with double waterproofed braid (or tape and braid) are generally used for conductors up to 600 volts and as large as 0000 B. & S. gauge. Varnished-cambric insulation is by far the best for larger cables and higher voltages, provided it is covered with good weatherproofed braid for protection against abrasion. Cambric-covered cables may be run in fiber ducts, if they are carefully drained. Cables for main connections of considerable importance are frequently installed with insulation suitable for voltages 50 per cent. in excess of the rated voltage.

Lead-covered cable used on a-c. circuits should be of the multiple-conductor type. Eddy currents in the lead sheaths of single-conductor cables increase the energy losses. Single-conductor lead-covered cables should not, in general, be used for heavy a-c. circuits.

Armored cables and conduits. On d-c. circuits, where maximum copper area is desired, single conductors should be used. Single-conductor cable is preferable for low-tension, d-c. mains on account of the simplicity of service connections. Concentric cables give maximum ampere capacity per duct for single-phase alternating current, but flat twin cables are usually more convenient and cheaper for mains and lines where the area is less than 250,000 circular mils. They are liable to kink and are not recommended in sizes larger than 250,000 circular mils. For two-conductor cables larger than 250,000 circular mils, either round cable (two conductors twisted together) or concentric cable is best. Triple conductor is almost a necessity in three-phase, a-c. work in order to avoid disturbance to parallel circuits and reduce loss in the lead sheath to a minimum. (If single-conductor lead-covered cables are used in a-c. circuits the sheaths should not be in contact nor connected by any low-resistance path.) Multiple-conductor cable is best for a number of small conductors run in one duct.

The cheapest cable insulation for UNDERGROUND CIRCUITS is paper and it can be used safely when the lead cover is not subject to corrosion. The insulation on sizes smaller than No. 6 B. & S. is likely to be injured by sharp bending or handling, and for smaller conductors, rubber insulation is best. It is also best for cables placed in very wet ducts, where severe corrosion is to be expected.

Thickness of insulation is principally dependent on mechanical requirements with low-tension cables (less than 1000-volt); for higher voltages the thickness is governed by the dielectric strength required. For 3-phase alternating current ungrounded or delta-connected, one-half the thickness of insulation should be put around each conductor and the other half surrounding the three conductors. This gives the same total thickness of insulation between conductors and between each conductor and ground. For 3-phase circuits Y-connected, with the neutral grounded, the thickness of the outer jacket may be reduced to roughly one-half the thickness of the insulation on the individual conductors,

since the pressure to ground is approximately 60 per cent. of the pressure between conductors.

Finish on cables in clean, dry ducts or wooden boxes underground or in any situation where the cable is not subject to mechanical injury or liable to corrosion should be plain lead. For wet ducts, or other places where corrosion (but not mechanical injury) is to be feared, and for burying directly in clean earth, with a protecting plank or tile laid above the cable, use a jute and asphalt jacket over the lead. When mechanical injury is to be guarded against, use band-steel armor over the jute and asphalted lead. If the cable is not to be supported practically continuously use wire-armored instead of band-steel armored cables. Such cable may be suspended for any practical distance, practically the entire strain being taken by the wire armor.

Current-carrying capacity of an insulated conductor is determined within practical limits by the maximum temperature the insulation will withstand. The temperature should not be above 85° C. for saturated paper, 75° for cambric, and 60° for rubber. The limit is lower for high voltage. The following maximum safe temperatures at the surface of the conductor in the cable are recommended in the Standardization Rules of the A. I. E. E.: For impregnated-paper insulation, $85-E$; for varnished-cambric insulation, $75-E$; for rubber compound insulation $60-0.25E$, where E = the effective operating voltage in kilovolts between conductors.

The maximum safe continuous load for any given cable is higher with direct than with alternating current, but the difference is of slight practical importance for conductors less than 500,000 circular mils in area. The safe load is less for 60 cycles than for 25 cycles; less in the tropics than in temperate zones; it increases markedly in winter; it decreases with the number of loaded cables adjacent to each other; *e.g.*, the average safe load in a four-duct line would be about 60 per cent. greater than in a 16-duct line; and cables immersed in water carry at least 50 per cent. more current than those buried in earth.

Table 29 shows the carrying capacity of different sizes of cables. The figures in the table are based on concentric stranded conductors. If solid conductors are used, reduce

Table 29. Allowable current in copper wire and cable

Size B. & S. gage	Circular mils	Amperes		Circular mils	Amperes

00	133,100	150	225	1,500,000	850	1360
000	167,800	175	275	1,750,000	950	1520
0000	211,600	225	325	2,000,000	1050	1670

the current given (for 30° C rise) by 7 per cent. For two-conductor cables, either round or flat, decrease the current given for single conductor by 15 per cent. For two-conductor concentric cables, decrease the current given for single conductor by 25 per cent. For four-conductor cables, reduce the current given for three-conductor cables by 12.5 per cent. For higher-voltage cable reduce table values by 1 per cent. for each 2000 volts that the working pressure exceeds 3000 volts; for example, 25,000 volt cable 11 per cent. less than the tabulated values.

For single-phase motors, multiply the current for three-phase motors by 1.73. For two-phase motors, multiply the current for three-phase motors by 0.886.

Power generation. The great majority of American ore-dressing mills of medium and large size operate electrically; public-service water-generated power is transmitted for this purpose as far as 175 miles (to Butte), 150 miles (to Mascot, Tenn.), and 100 miles (to Tonopah), while transmission of 50 to 75 miles is common.

Hydro-electric generators are rarely warranted for an individual mill of short or unknown life owing to the heavy expense usually required for storage reservoirs, although the generating station itself may be no more expensive than a steam plant of corresponding size.

In the rugged and rainy coasts of British Columbia and southern Alaska exceptionally favorable hydraulic conditions justified several of the large mining and milling companies in erecting water-driven generators. The total cost of hydro-electric plants (before 1917) including dams, ditches, and all equipment, was estimated at $100 to $200 per kw. capacity (*Peele*). On the score of reliability of operation, a hydro-electric plant is equal to steam and superior to gas-engine, the most common source of delay being ice at the intake; a long transmission line, however, is always subject to interruption.

Steam generation in plants designed for the utmost efficiency is the usual practice at many large mills in the United States, and steam generation is usually preferred at small mills where first cost is considered more important than fuel economy. Coal or oil is used as fuel, depending upon availability; the convenience of the latter may offset higher unit cost. The plant should be designed to furnish power at a minimum cost per hp.-hr. delivered (not rated output), including interest and amortization of plant within the life of the mill. The necessity for uninterrupted service may justify a greater outlay than would be warranted on grounds of fuel or labor economy.

The essential elements of a steam plant are boiler, engine and feed-water pump; further equipment intended to economize fuel or labor, stated in the order in which it is usually adopted, is feed-water heater, compound engine, condenser, superheater, automatic stoker (*107 J 1121*). Fuel economy and reduced cost per unit of power generated are thus gained at the expense of simplicity (entailing more skilled supervision) and of original outlay. Turbines are cheaper and simpler than reciprocating engines, but require more skilled supervision. The cost of steam-driven generating plants (before 1917) including buildings and all equipment (*Peele*) varied from $90 to $140 per rated kw. for reciprocating engines, and from $40 to $90 per rated kw. for turbines.

Diesel engine has about the same weight and cost, per unit of installed power, as a steam-engine plant of the more elaborate types; it is particularly noteworthy for its high fuel efficiency up to the safe limit, which is fixed by the weight of air that can be admitted to its cylinders, but it is incapable of carrying sustained overloads. It requires skillful supervision, and repairs and renewals constitute a large item of expense, which, however, can be diminished by regular replacement of worn valves, etc., before failure. Its best field is at plants of moderate size, where coal would be uneconomical and fuel oil expensive; its consumption averages only 30 to 40 per cent. of the amount required at a high-class oil-fired steam plant of corresponding size.

Notable installations of Diesel-driven generators have been made by the Phelps Dodge Corp. at Tyrone, Morenci, Globe, and Nacozari. Those at Tyrone, at 5950-ft. elevation (*119 P 369*), are vertical, 2-cycle, with 5 cylinders 20.6-in. diameter and 26-in. stroke; speed, 180 r.p.m.; rated at 1250 brake hp. at sea level. The scavenger pump is large enough to maintain a pressure of 2 to 3 lb. per sq. in. in the cylinder at the beginning of the stroke, thereby simulating sea-level conditions; this plan increases fuel consumption per available hp., but makes the total cost lower by permitting investment in a smaller engine. A compressor for the oil injector, and to store compressed air for starting, is direct-connected to the engine. Each engine is direct-connected to a 60-cycle alternator of 815 to 850 kv-a.

capacity. Fuel is the same quality as that used under steam boilers, California 14° to 20° Bé. occasionally carrying 2 per cent. sulphur; some oil of 24° Bé. is fed just before stopping an engine, so that its first supply on starting will ignite more readily. The heavier oil is warmed by coils carrying cooling water from the exhaust jackets of the engines. Fuel consumption, per hour, varies directly with the load, from 175 lb. at 100 kw. to 420 lb. at 600 kw.; above that point, consumption increases somewhat more rapidly, being 570 lb. at 800 kw. A steam plant with the same output as the Diesel engines at Tyrone is estimated to require five times more water, 2¼ to 2½ times more fuel, but only one-third as much expense for repairs and replacements. Costs for labor and miscellaneous supplies are practically identical. A IRON MT., Mo., two 500-hp. Diesel engines drive two 436-kv-a. generators at 2300 volts. The cost of the whole plant (1923), including building and all accessories, erected and running, was $100,000. Operating at half capacity, with oil at $1.65 per bbl., the cost was 1.78¢ per kw.-hr. including interest and amortization (15 yr.). BETTY O'NEAL mill (and mine) Lewis, Nev., operates two Fairbanks-Morse 6-cylinder semi-Diesels of 300- hp., each direct-connected to a 200-kw., 460-volt alternator of 60 cycles. Fuel is 27° Bé. distillate, costing 7.1¢ per gal. at the mine; each engine consumes 17 gal. per hr. The total power cost is $6 per hp.-month (*117 J 449*). Cooling water from the mine is chemically softened before use.

8. Lighting

Artificial lighting (*E. Bachman, PC*) is necessary for safety and to enable workmen to inspect operations. The usual practice is to install a lighting circuit of 110 volts with separate transformer, or an individual dynamo so that lighting need not be subject to interruption. It is possible to secure lamps for 220-volt circuits but these are not so efficient, sturdy or generally useful as 110-volt lamps. Exposed wires are permissible in a steel structure; iron pipe or flexible metallic conduit is safer for wooden mills.

Incandescent lamps of high intensity on series circuits are installed at UTAH CONSOLIDATED, CHIEF CONSOLIDATED, SILVER DYKE, U. S. SMELTING R. & M. CO. and other mills. This system is more efficient, lower in first cost, and easier to maintain than multiple systems. The layout is the same as for multiple circuits, except that series sockets, lamps, and reflectors such as are used for street illumination are necessary. Lead-covered, single-conductor cable, No. 8-gage is most economical, since it can be run on girders, etc., without insulators or pipe conduits. For comparative efficiencies of the two systems, see Fig. 9. Series circuits are fully safeguarded from the effect of high voltage coming from

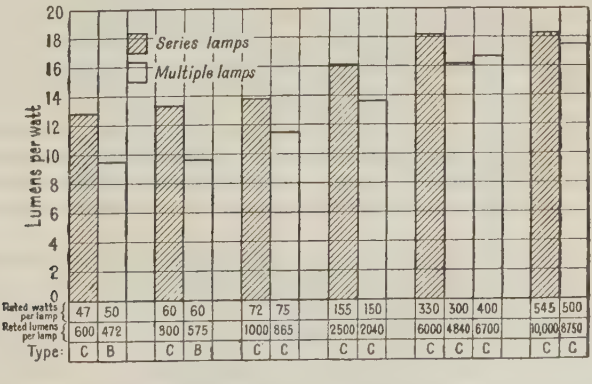

FIG. 9.—Relative efficiencies of multiple and series Edison Mazda lamps.

an open-circuited secondary, lamp burn-out, etc., by suitable protective devices. Lamp operation is protected by a film cut-out in each socket. In case a lamp burns out, the film cut-out is punctured in the socket, which permits current to flow through the circuit without interrupting the operation of other lamps.

Methods of illumination (*123 P 751, 61 EW 628, 70 EW 6, 201; 72 ER 907, 9 Trans. Illum. Eng. Soc., 814*). In a small mill, 50-watt lamps or larger, with reflectors and waterproof sockets, are suspended by cords, wherever needed; they should be within reach for easy cleaning and replacement, and the number should not be stinted. With power at 1¢ per kw.-hr., the total cost for lighting with Mazda lamps (including replacements) is 4¢ to 5¢ per 1000 candle-power-hours (c-p.-hr.) One c-p. = 0.75 watt in this type of lamp. Globes and reflectors should be kept clean. Theft-proof sockets are on the market. Drop lamps are necessary for close work, but produce glare, which reduces acuity of sight and tires the whole body. Breakage of lamps is liable to be excessive and the cost of wiring is high. General illumination with a relatively small number of large, efficient lamps is now in extensive use for all types of industrial lighting and is well suited to large ore-dressing plants. When the arrangement of a mill is such that the greater part of the area needs only relatively low intensity of general illumination, but some few operations require much higher intensity, the most economical plan is to supplement overhead lighting with local lamps judiciously placed, *e.g.*, at tables and jigs. In some of the most modern plants portable lamps are issued in the same way as special tools and conveniently located wall outlets are installed for attaching them.

Types of lamps. The inside-frosted Mazda C lamp is most generally applicable for general illumination. It is efficient and sturdy; the smooth white mineral coating on the lower portion of the bulb diffuses the light, eliminates glare, and makes the shadows soft and feathery rather than dense and harsh. Special features of construction, such as the short stem and flexible supports, give these lamps greater strength than the old Mazda B lamps.

Cooper Hewitt mercury tubes have proved satisfactory at MIAMI and other large mills. They are particularly useful where it is difficult to recognize the valuable minerals by incandescent light. Iron arcs are used at the Franklin plant of NEW JERSEY ZINC CO. to show apple-green willemite on the tables.

Reflectors. The RLM standard dome reflector is most used for general or localized general illumination. It gives a desirable distribution of light with adequate illumination on vertical surfaces, is efficient, easy to clean, and so designed that direct glare is reduced to a satisfactory minimum. The deep-bowl metal reflector gives a lower cut off. This tends to reduce the amount of light on vertical surfaces and although there may be excellent illumination on the working plane a room often appears dull. The deep-bowl reflector is especially serviceable in local lighting with low-hung lamps. Angle metal reflectors are used where especially high illumination is required on vertical surfaces and where lighting units must be located on the side walls. They are frequently placed below a crane track and should generally be supplemented by overhead units.

A number of types of metal reflectors specially designed for industrial lighting provide additional means of diffusing the light. Sometimes a polished-metal cap is placed over the lower half of the lamp bulb to cut off the direct light. Diffusion is sometimes accomplished by opal-glass diffusing caps, and some devices employ a shield of metal on the level with the filament. If the reflector itself is properly designed, these additional accessories tend to eliminate sharp shadows and annoying reflections from the work at a reduction in total output of light and a somewhat higher cost of equipment. Prismatic, mirrored, and dense opal, deep-bowl glass reflectors are also used. These may be very efficient and give suitable distribution of light. The translucent types produce a bright, cheerful room. While it is evident that breakage is likely to

be greater than with metal reflectors, the hazard is not so great as often assumed. Enclosing, or semi-enclosing units of opalescent or diffusing glass find quite an extensive application; they produce excellent diffusion with slight sacrifice of efficiency.

Lamp spacing. The standard dome reflector and bowl-enameled Mazda C lamp have become almost standard equipment for mill lighting. Assuming this unit gives out a certain definite amount of light the advisable spacings of different sizes are as shown in Table 32.

9. Heating

Heating of mills in cold climates is necessary not only for comfort but to avoid delays due to freezing. Practically every important mill in the United States, except a few in the Southwest, makes special provision for heating during the winter; in some cases, stoves are sufficient, in others exhaust from steam engines is utilized, but the general practice is to install radiators connected to steam boilers set aside for this purpose.

In Ontario, heating during 5 to 6 months of the year becomes a heavy item of expense. At McIntyre-Porcupine, treating 241,000 tons, the annual heating cost is $15,000, or 5.6 per cent. of the total milling expense; at Nipissing the annual cost for heating the low-grade mill is $22,000, or 6.3 per cent. of the total milling cost for 82,000 tons.

Steam-heating system for mills in the western and north-western United States may be designed on the following principles: (*a*) An average radiator surface of 1 sq. ft. (with steam at 5-lb. pressure) suffices for 160 cu. ft. of mill interior; in a terraced mill, radiator area in the lower sections should be somewhat above average, and less than average in the upper sections. (*b*) Based on the area of radiators alone, the boiler rating should be 1 hp. per 50 sq. ft. (*c*) Including the radiating surface of supply- and return-steam lines, 1 boiler hp. per 80 sq. ft. of total radiating surface is usually ample. (*d*) Cost of radiators, pipe and installation, but not including boilers, is 0.4 to 0.5¢ per cu. ft. of mill interior. (*e*) A reducing valve set to deliver at, say, 5-lb. pressure, should be placed in the supply main ahead of the first radiator branch. (*f*) A drip pocket, connected to a steam trap, should be placed in the high-pressure line near the

boiler, or at any other low points in that line. (*g*) A steam trap should also be attached at the end of the return line, delivering its water to the sump for the boiler-feed pump; at a small mill or at one having no parts subject to a sudden drop in temperature, the return line may lead directly to the boiler.

Design of radiators. (*a*) A continuous-pipe radiator, with U-joints, requires no left-hand threading, and is cheap and easy to construct; where large heating effect is required, this design is objectionable in that the cumulative effect of condensation may overload the lower pipes in the series with water and retard steam circulation. (*b*) A grid of radiator pipes rigidly connecting two parallel headers requires right- and left-hand threading, is difficult to make tight at all joints, and is likely to develop leaks with unequal expansion; pipes can be welded into a wrought-iron header by a skillful operator, but the expense is likely to exceed that of threading and tapping. (*c*) The design shown in Fig. 10 has the advantages of using only stock materials (headers are cast-iron), being easily and quickly constructed, and having ample allowance for unequal expansion; the latter provision could also be made, with parallel headers, by a right-angled bend, setting the radiator in a corner. For stated lengths *A*, the amounts of 1-in. pipe and the total radiating areas are as given in Table 33.

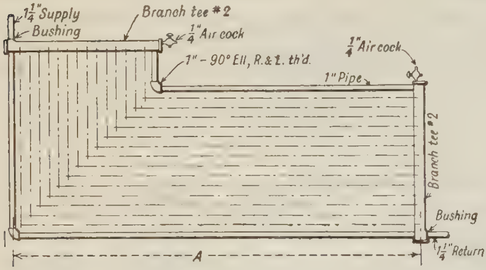

FIG. 10.—Outline sketch of mill radiator.

Table 33. Data for radiator shown in Fig. 10

A, feet	1-in. pipe, linear feet	Radiation, square feet	Cost (1924), complete
10	168	56	$63.25
12	200	67	67.05

Radiator fittings	Connecting fittings
2 Crane c.-i. branch tees No. 2, with 16 @ 1-in. branches, ¼-in. tap at inlet end, 1½-in. tap at outlet. 2 Bushings, 1½- to 1¼-in. 2 Air cocks, ¼-in. 16 @ 1-in. 90° ells, right- and left-hand threaded. 8 Hook plates for 1-in. pipe, 4 hooks each, spaced 2½-in.	2 Kewanee unions, 1¼-in. 2 Gate valves, 1¼-in. 3 Standard 90° ells, 1¼-in. 2 Street 90° ells, 1¼-in. (The above fittings allow for a swing joint in the supply line, and one ell in the return line.)

Table 34 gives the radiator areas that can be adequately supplied with steam at 5-lb. pressure through supply pipes of stated lengths and diameters; also the diameters of suitable return lines. Knowing the total radiator area and the distance from mill to boiler,

the necessary sizes of supply and return lines can be calculated. In similar manner, the diameters of branch lines serving different sections of a large mill can be estimated.

10. Fire Protection

Fire protection in a wood-frame mill should include as many of the following precautions as necessary: (*a*) Portable extinguishers, desirable in all mills. (*b*) Automatic water sprinklers, advisable in all wooden mills of large extent. If sprinkler lines are liable to freeze, the dry system of control must be installed. (*c*) Fire mains under constant pressure and used for no other purpose, with hydrant valves at frequent and convenient intervals, to which hoses and nozzles or monitor nozzles are permanently connected; this system is considered adequate for small mills, and may render the installation of a sprinkler system unnecessary. (*d*) Well organized and regularly trained force of fire fighters, without whom the most elaborate system of equipment would be of little value in an emergency. (*e*) Cleanliness in the use of flotation and lubricating oils, with special precautions against accumulations of either. Advice on the general problem of fire protection, as well as detailed specifications for the most suitable installation in a given mill may be obtained gratis from: National Board of Fire Underwriters, New York; State boards of insurance inspectors; reputable fire insurance companies, all of whom maintain engineers for this express purpose.

Portable extinguishers have important advantages for protection of mills, since during two-thirds of the day the number of men who can be instantly summoned is reduced to the minimum required for the supervision of operations. In a wooden mill, the points that should receive best protection are: vicinity of flotation-oil feeders and storage, boiler rooms, store rooms, electric switchboards, and the neighborhood of all equipment requiring copious lubrication.

Soda-acid, 2½-gal. extinguisher is satisfactory for small fires in wood, rubbish, etc., not impregnated with oils or grease, but should not be used against fire in proximity to high-tension electric circuits; it must be protected against freezing. It is made also in 20- and 40-gal. sizes mounted on wheels.

Anti-freezing. 2½-gal. tank contains calcium chloride solution which is discharged by pressure generated by an automatically ignited cartridge; this has the same limitations as the soda-acid type, but does not require protection against cold.

Foamite extinguishers in 2½-gal. hand tanks and 40-gal. wheel-mounted tanks, contain solutions of aluminum sulphate, sodium bicarbonate, and a froth stabilizer (licorice extract). On mixing these solutions by inverting the tank, a frothy stream having about eight times the original bulk is discharged. The smothering effect is due to tenacious bubbles of carbon dioxide aided by films of aluminum hydroxide. It is suitable for ordinary fires, and particularly for those involving oils and grease, but is not safe for fires near high-voltage electric circuits although the stream of foam, after the momentary discharge of ungasified solution, is a poor conductor; foamite does not injure electric insulation. Foamite tanks must be protected from freezing.

Carbon tetrachloride is the only fire-extinguishing medium that can be used with safety around high-tension electric circuits. For other fires, including those in oil or grease, it is also serviceable, but the small size of the containers adopted by manufacturers (usually 1 or 1½ qt.) limits its effectiveness on a fire that has gained much headway, while the necessity for pumping the container is also a drawback to its efficiency. Larger containers are being developed. The tetrachloride supplied by extinguisher manufacturers contains ingredients to reduce its freezing point, and no protection against cold has to be given; no other than the special tetrachloride should be used. In the vicinity of electrical equipment or oil supplies, a unit of two tetrachloride extinguishers should be provided for 2500 sq. ft. of floor, and within 15 ft. of any specially hazardous point.

Automatic sprinklers, held closed by fusible links, are recognized by insurance companies as the most efficient form of protection against incipient fires. If sprinklers are installed, the standpipe and hose equipment may safely be reduced. The following recommendations apply particularly to the type of construction commonly found in wood-framed mills (*Regulations of the National Board of Fire Underwriters governing the installation of automatic and open sprinkler equipment; New York, 1922*):

(*a*) The entire mill should be equipped with sprinklers, not merely that portion where fire is most likely to begin; any unsprinklered areas must be cut off by fire-proof walls. (*b*) Sprinklers must be in upright position (deflector on top), must have 24 in. of wholly clear space below them, and should be 6 to 8 in. below the ceiling or the bottom of joists. (*c*) One sprinkler must be provided for 80 sq. ft. of area, spaced, say, 8 ft. on lines 10 ft. apart, the sprinklers being in staggered rows. No sprinklers should come within 12 in. of a post, hanger, or other vertical obstruction, nor within 2 ft. of wall or partition. (*d*) Under pitched roof, one line of sprinklers should be installed under the peak, or two lines each not more than 2½ ft. from the peak. (*e*) The maximum number of sprinklers to be served by pipes of stated sizes is given in Table 35. Preferably, no branch line should carry more than eight sprinklers. (*f*) Reducers, not bushings, should be used for connecting pipes of different size; couplings should not be used unless practically unavoidable. (*g*) DRY-PIPE SYSTEM should be adopted only in those parts of a mill where water pipes would be liable to freeze; the air capacity of a dry-pipe system controlled by a single valve should not exceed 115,500 cu. in. (*h*) The air pressure in a dry system (maintained by compressor) should not be more than 15 to 20 lb. in excess of the normal tripping pressure of the automatic water valve; the dry system should not leak more than 10 lb. pressure per week. (For detailed specifications, see the cited publication, obtainable on request.)

Table 35. Size of pipe and number of sprinklers

Pipe, inches	Maximum number of sprinklers	Pipe, inches	Maximum number of sprinklers
¾	1	3	36
1	2	3½	55
1¼	3	4	80
1½	5	5	140
2	10	6	200
2½	20		

Water mains exclusively for fire-fighting purposes should be connected with tanks of ample size (50,000 gal. at TIMBER BUTTE) maintained constantly at full capacity; this is conveniently arranged by setting the fire tank first

in series with the mill-water tanks and allowing it to overflow into them. Fire mains should also be connected with other sources of water supply available either instantly or by starting special fire pumps. If connection for this purpose must be made between the mill system and the domestic supply of the community, precautions must be taken to avoid contamination of the latter by installing a tight check valve which will not yield until the pressure on the mill side is considerably below that on the domestic side (this valve must not be forgotten during any readjustments which may affect the pressure on either side); a safer method is to discharge the domestic water into the fire tank from an open pipe.

A minimum pressure of 75 lb. per sq. in. should be provided for the highest fire-hose connection. Mains and principal hydrants should be situated at least 50 ft. outside the mill; near the most hazardous points inside the mill, other connections should be provided for lines of 1 ¼- or 1 ½-in. hose, which is as large as one man can handle at adequate protective pressures. Hose permanently connected to outside hydrants, not over 100 ft. in length (but with other 50-ft. lengths at hand), should be of standard 2- or 2½-in. size without rubber. The standard Nozzle for this hose has 1⅛-in. orifice (passing 250 gal. per min. at 45-lb. nozzle pressure), but with the higher pressures available at a well protected mill, orifices of ¾- and 1-in. are sufficient. For the smaller hose, the nozzle opening should be ½-in.

Fire-fighting forces are of little use unless well organized and thoroughly trained by frequent practice. Every member should be instructed in the manner of reporting a fire, use of portable extinguishers, the location of hydrants, the fire-piping system and the inter-relation of its valves, the water resources at immediate command and methods of adding to them. All of this information can be best communicated by printed instructions, as at Timber Butte mill (*116 J 811*), supplemented by regular practice drills with teams so organized that a sufficient number of trained men will be on duty every shift. Suggestions for organization and training are published by the National Board of Fire Underwriters.

Cleanliness, always desirable on general principles, is particularly necessary at those parts of a wooden mill subject to spillage of lubricating and flotation oils. Journals that require frequent oiling should have drip pans or similar devices. Feeders for flotation oils should be similarly equipped. In a small mill, where flotation oils are transferred directly from barrels to the feeders, the area of floor used for this purpose should be covered with sheet iron with raised edges; sand is then spread on the floor, to be shoveled out and replaced as often as necessary.

11. Dust collection

Dust is likely to be produced in troublesome amounts by almost any operation (crushing, screening, elevating, etc.) performed on material carrying less than 7 per cent. moisture. If allowed to migrate freely, it is chiefly objectionable because of disagreeable or unhealthful working conditions, increased abrasion of lubricated bearings, expense for cleaning floors and equipment and possible loss of valuable ore. Motors are the most seriously affected; they can be somewhat protected by grouping in an isolated room and driving the mill by line shaft, or by interposing an extra long shaft between a piece of equipment and its direct-connected motor, which can then be situated in an adjoining and dust-proof room, as in the Symons crushing department at Ajo (*114 J 184*). The most satisfactory method of control is to confine and collect the dust at its sources; the worst dust-producing

machines, as a rule, can be enclosed readily with sheet-metal housings connected with an exhaust system, with or without appliances for recovering the dust.

Where collectors have been installed, as at Kalgoorlie, and Waihi (*114 J 1070*), and at Morenci and Nacozari (*117 J 165*), the value of the dust, which usually assays higher than the original ore, has been more than enough to defray the whole expense of its collection.

Design of suction system. The following points were established at Morenci in 1917 (*22 CME 207*). The hood should be so designed that the sum of its air inlets does not exceed the area of its exhaust pipe. The exhaust pipe should be attached at that point of the hood towards which the dust is naturally impelled by centrifugal or other forces or by air currents. Connections between the hood and the suction pipe should be by bolted flanges, to permit quick dismantling; other joints in the suction line should be riveted and soldered, with laps in such direction as to cause minimum friction. A velocity of 4000 ft. per min. will carry any ordinary dust. A main header should increase progressively in area, always being slightly larger than the sum of its branches. The system as a whole should be designed to maintain the desired velocities in mains and branches without recourse to valves and dampers for regulation. For straight pipe, 16- or 20-gage galvanized steel is best; on curves, 16-gage. Radius of bends (measured from the center line) should not be less than 1 ½ times the diameter of the pipe, but there is no advantage in a radius greater than twice the diameter. Unless the headers are equipped with hopper pockets and gates at short intervals, they, as well as all other pipes, should have an inclination of 30° or more (preferably 45°) to allow dust to be withdrawn on stopping operations. The simplest mechanism for recovering dust is a dry cyclone separator; this will catch 75 to 80 per cent. of any ordinary dust. Of the remaining finest particles, 98 per cent. can be caught in a cloth-walled chamber, bag house, or wet centrifugal collector; the expense of a Cottrell precipitator will not usually be justified for this purpose.

At a dry-crushing mill at Kalgoorlie (*114 J 1070*) one 36-in. Sturtevant suction fan, at 1000 r.p.m., drawing 5000 cu. ft. of air per min., collects dust from six large crushers of Griffin, Krupp, or Symons type. Branch pipes are 9-in. diameter; main header, 18-in., equipped with V-traps and vertical risers for collection of the coarser particles. The dust assays higher than the original ore. It is caught in a cyclone collector followed, by a chamber having double walls of fine burlap, with rapping devices, and hoppered bottom with screw conveyor. The original installation at Arizona Copper Co., Morenci, in 1917 (*22 CME 207*), when crushing 250 tons per hr. to ¾-in., the ore averaging 3.85 per cent. moisture, required seven hoods to cover one gyratory and grizzly, two horizontal disk crushers, and two pairs of rolls. The suction pipes were 8-in. diameter, except that from the gyratory hood, which was 10-in. The wet collector was a cylindrical tank of 3⁄16-in. steel, 10.5 ft. diameter by 15.5 ft. tall, with tangential inlet near the top. The exhaust, through the top, came from inside a cylindrical shroud, 7 ft. diameter, extending down to within 6 ft. of the bottom of the tank. Water sprays impinged against this shroud, inside and out, and muddy water collected in a concrete basin on which the tank rested, flowing out through a water-sealed trap to flotation. The suction fan, following the wet collector, was a Sturtevant No. 70, exhausting 11,100 cu. ft. per min. at 577 r.p.m., and 3.5-oz. negative pressure; motor input, 23 hp. The dust collected was 0.0367 per cent. of the weight of ore crushed, assayed 2.34 per cent. Cu, and consumed 6552 gal. of water per ton, which was probably more than actually necessary. A later installation by Phelps Dodge Co. (*117 J 165*) has two similar units each comprising a motor-driven Sturtevant fan No. 80, dry collector and wet collector. On fairly dry freshly-mined ore, the system collected 8 to 10 tons of dust per shift (80 per cent. from the dry collector), of which 1 per cent. was coarser than 65-mesh and 93 per cent. finer than 200-mesh; its assay was about double that of the original ore. Each wet collector used 10 gal. of water per min. When working on oxidized ore from the stockpile, about twice as much dust, of the same fineness, was collected, its assay being the same as that of the ore. At Nacozari, a similar but smaller installation collects three tons of dust per shift, produced entirely by coarse crushing, and assaying twice as much copper as the original ore. At a rock crushing plant at Corona, Cal. (*116 J 889*), trommels are enclosed in jackets connected by suction pipes to two Sly type-A units, each having 3000 sq. ft. of filter cloth and passing 10,000 cu. ft. of air per min. They collect 1.5 tons of dust per hr., coarse particles having been settled previously in a baffled chamber. Suction is stopped for 10 minutes every 4 hours to rap the filters. At United Verde crushing plant, Clarkdale, Ariz. (*117 J 396*), dust is withdrawn from groups of four jaw crushers, four vibrating screens, four disk crushers, and four rolls, by a separate duct from each group. The ducts have cleaning pockets and gates every 15 ft. Fine dust is caught by plate-and-wire Cottrell precipitators, collected in hoppers and discharged into cars delivering to roasters. A negative pressure of 6-in. water-gage is produced

by two 45,000-cu. ft. fans, each direct-connected to a 125-hp. motor. At Ajo leaching plant (*114 J 184*), disk crushers stand above a tunnel containing a belt conveyor on which the crushers discharge; when operating, the ends of the tunnel are closed by doors, and air is exhausted by a suction fan delivering to a group of cyclone separators.

12. Shops, repairs, supplies, etc.

Character of shop work. At an operating mill, shop work is confined almost exclusively to repairs; while a mill is under erection, however, the shops are a most valuable adjunct, and may well be the first buildings set up. A long, simple structure can be partitioned off, the most convenient arrangement being, starting at one end: office, warehouse, machine shop, carpenter shop. Blacksmith work can usually be done most conveniently at the mine shop. The scope of work to be arranged for depends on the size and elaborateness of the mill, and its situation with respect to other established shops capable of doing at least some of the required work. The foundries and machine shops of an enterprise like Utah Copper Co., for example, providing for the operation of mines, railroad, and two large mills, compare favorably as to size, arrangement, and completeness with the best industrial machine works. A small mill in an outlying district would be justified in the installation of fairly complete shop machinery, even if not all continuously occupied, so as to save time in repairs and avoid some duplication of expensive mill equipment to guard against delays. Some means of transferring parts of heavy mill equipment into the shop without excessive effort must be provided by car tracks, crane, or both.

List of equipment for a machine shop for a small mill: Hand punch and shear; lathe, 18-in. swing, 8- to 10-ft. bed; pipe-threading machine, 1¼ to 4 in.; oxy-acetylene torch outfit complete; bolt- and pipe-threading machine for ½- to 1½-in. bolts and ⅜- to 1-in. pipe; electric- or air-driven hand drill; portable forge, anvil and blacksmith tools; radial drill press, 48-in.; power hack saw. The usual assortment of hand tools, vises, benches, etc. The carpenter shop, besides benches and hand tools, should have a saw bench with 16-in. circular saws and a buzz planer.

At one large mill in the Southwest, the following machine tools, all with individual motors, are installed: 27-in. × 28-ft. lathe, 14-in. × 12-ft. lathe, 6-ft. radial drill, 16-in. spindle drill, 28-in. swing drill, 100-in. boring mill, 42-in. × 12-ft. planer, 24-in. shaper, No. 2 and No. 6 pipe machines, friction saw, punch and shears, blacksmith forges, welding equipment. One five-ton crane serves these machine tools. A five-ton crane and a sixty-ton crane with a ten-ton auxiliary are installed over the secondary ball mills to carry loads from the mill to the machine shops which are nearby.

Repairs, in most case, must be made without moving the machine from its place; small repairs can be made by the mill crew, who should be provided with benches and hand tools at convenient places in the mill. Worn parts of crushing machines can usually be repaired more conveniently in the shop, where screw-jacks, hydraulic presses, etc., are available. With such machines, the best practice is to keep one or more spare parts on hand, assembled and ready to install; this applies particularly to gyratory spindle and crushing head, rolls, cylinder-mill scoops, and entire mills.

Cranes or crawls are essential in every part of a mill containing equipment too heavy to be lifted by rope or chain tackle and temporary staging; they also avoid the trouble and delay in erecting the latter, even where they might be strong enough. The usefulness of a crane begins while a mill is under construction, and it should be installed as soon as the columns and beams are in place. Care should be taken to insure that the crane is able to reach every unit of equipment it can advantageously serve, including motors, cylinder-mill scoops, classifiers, heads of elevators, pumps, etc., in addition to the heavier crushing equipment. A crane should also be able to travel either

into the repair shop or far enough to deliver its load to a car or another crane serving the shop; if possible, the cranes in those parts of a mill having the heaviest equipment should reach also the railroad or supply yard.

At the UNITED COMSTOCK (*114 J 846*, *117 J 516*) the coarse-crushing department, containing No. 7½ gyratories, 72-in. rolls, and 200-hp. motors, has a 20-ton crane reaching the railroad and the working space between the shops; the fine-crushing section, with 7 × 6-ft. ball mills and 150-hp. motors, also has a 20-ton crane traveling over the supply yard and into the shops; the cyanide department, with basket filters aggregating 74,400 sq. ft. of filtering surface, contains two 40-ton traveling cranes. The COPPER QUEEN mill at Bisbee has an unusually complete equipment of electric cranes, as shown in Table 36.

Table 36. Cranes in Copper Queen mill

Serving	Span of craneway, feet	Lifting capacity, tons
1 jaw crusher, 66×84-in.; 250-hp. motor	75	50
2 gyratories, Gates No. 9; 2 motors, 125-hp	39	20
4 Symon's disks, 48-in.; grizzlies, etc	38	20
8 Marcy rod mills, 6½×12-ft	30	60 (2 hoists)
40 Deister tables, Dorr classifier, etc	28.5	5
8 Marcy rod mills, 6½×12-ft., classifiers, etc	30	60 (2 hoists)
Callow flotation cells; 1256 sq. ft of bottom	37	5
80 Deister tables, etc	37	5

Hand-operated chain blocks are available with lifting capacities up to 20 tons and reaches up to 18 ft.; small, self-contained electric hoists, for suspending from girders, have capacities up to 10 tons with a lift of 10 ft. The simplest crawl consists of a 4-wheel trolley truck running on the lower flange of an I-beam; trolleys for loads up to 10 tons are on the market.

Warehouse and supply department is essential to efficient operation; under competent administration it reduces waste, facilitates cost accounting, and avoids loss of operating time resulting from lack of necessary materials. The warehouse should adjoin the railroad and be as close as practicable to the mill and shops. Materials regularly consumed, such as balls and pebbles, flotation oils and reagents, should be stored as near as practicable to the places where they are used, though still under the jurisdiction of the storekeeper; other supplies, used intermittently, should be kept in the storehouse and issued only on requisition. Paints, lubricating oils, and similar highly inflammable materials should have a separate fire-proof storage. Lumber should be protected from weather.

13. Methods of practical design

Preliminary layout. A FLOW-SHEET is the first requisite. This must have been exhaustively studied and thoroughly and finally decided upon in respect to every important detail, including: number, types, sizes and capacities of individual machines; their relative positions with respect to one another; quantities of ore and of water in transit at every point throughout the mill; power required by every machine; number, sizes and types of all motors and the speed reducers connected with each. The design of the flow-sheet will be based on the results of laboratory or pilot-mill experiments, interpreted in the light of experience, and will be guided by the available supply of water, sources of power, type of mill structure applicable to the site,

and other practical considerations. A TOPOGRAPHIC MAP of the site is required, not only to select the general type of structure, but to determine the amount and character of the required excavations and the placing of walls, foundations, etc., so as to reduce the amount of this work, after the manner of a railroad location. The map, which will usually have been made early in the investigation, should cover a sufficient area to allow a choice among equally accessible sites and permit the final and precise selection to be deferred until the more important structural features have been determined. PRELIMINARY SKETCHES in three projections, not necessarily to scale, are a valuable means of crystallizing ideas, gaining a sense of proportion, and transmitting suggestions for execution of the next step. PRELIMINARY SCALE DRAWINGS should be confined to outlines, preferably on a scale of $\frac{1}{20}$ in. to the foot; adoption of this small scale protects the draftsman from the constant temptation to go too far into detail, thereby obscuring general features. The three projections of these drawings should appear on a single sheet, so as to give better idea of space proportions. On these drawings, the draftsman should prepare and make constant use of templates representing the outlines of individual machines or groups of closely related machines, such as rolls, elevator and trommel; ball-mill, motor and classifier; these templates (used under transparent paper) not only save much time during the initial period when erasures are likely to be frequent, but are of great assistance in fixing the most advantageous position of the equipment. PRELIMINARY ESTIMATES of structural elements can be made from these small-scale drawings. These estimates, as well as those that follow, and all calculations on which they are based, should be preserved in bound notebooks (conveniently 8×10 in. or larger).

Detailed general drawings, in three projections on a scale of $\frac{1}{8}$ to $\frac{1}{4}$ in. to the foot, depending on overall dimensions, must be complete as to every item, and show as much detail as possible at that scale. Nothing having any bearing on the erection of the building and installation of machines should be omitted; the more complete these drawings, the quicker the construction can be finished and the less the chance for overlooking essential features. Among the items that must be plainly shown on the general drawings are: foundations and floors, frame, walls and roof, windows, cranes and crawls, all machinery, motors and drives, shafting, clutches and pulleys, launders and pipe lines. A small mill should be drawn in entirety, a separate sheet for plan, front elevation, and end elevation or sections; for a larger mill, a typical unit will suffice at this larger scale, if accompanied by a complete assembly at a smaller scale.

Construction details. The amount of large-scale drafting of structural details depends upon the size of mill and type of construction. The following detailed drawings should be supplied for all mills: (*a*) EXCAVATIONS: volume and character. (*b*) FOUNDATIONS: footings, dimensions and batters, copings, reinforcements, drains or "weep" holes, elevations of the top of each wall, pier or foundation above the datum plane, and the position of anchor bolts. (*c*) MECHANICAL EQUIPMENT: where machines of standard types and sizes are adopted, dimensions and foundation plans of which are supplied by manufacturers, the drawings to be made for construction purposes will relate mainly to their support and the facilities for conveying ore to and from them; for the installation of the large variety of other equipment, such as trommels, elevators, conveyors, feeders, distributors, samplers, and all other devices that must be adapted in size and arrangement to suit the particular mill, com-

pletely detailed drawings should be prepared, including their connecting elements. (*d*) Shafting and all its appurtenances, including hangers or pillow blocks, journal boxes, clutches, pulleys, collars, and couplings; descriptions of all these elements should appear as completely as possible on the drawings, so that the accompanying written specifications need be little more than a reference list. (*e*) Piping system as a whole can be shown most easily and clearly by an isometric projection (see Fig. 11), on which the dimensions of all main and branch lines, valves and fittings can be indicated; for minor details of particular connections, a sketch on larger scale should be appended as an insert on the main drawing. (*f*) Launder system must be worked out in all its details and subjected to careful scrutiny as to the ability of each member to carry the desired volume of its given pulp; this is a particularly important feature of design, and should not be left to the discretion of the millwright, since a launder once installed at too low a slope is difficult to reconstruct. (*g*) Wiring diagram, conveniently indicated by colored lines on a copy of the general drawings, should state the sizes of conductors, character of insulation, position of switches, fuses, lights, etc.

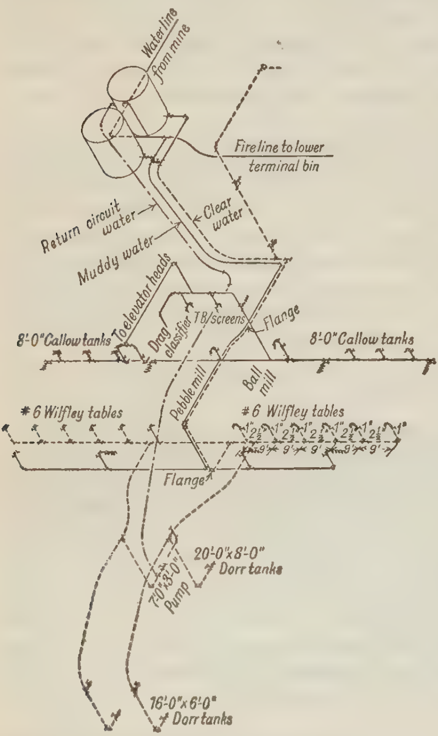

Fig. 11.—Typical arrangement for lay-out of mill water piping.

Steel structures. It is rarely necessary for the mill designer to prepare detailed structural drawings for steel work. If the plant can be protected by one or a group of simple rectangular buildings, these can be purchased ready-made from a number of fabricators. For a larger and more complicated structure, the usual procedure is to prepare several sets of general plans, accompanied by a statement of the roof load, floor load, crane capacities, character of wall material, etc., and submit these to steel-work fabricators, who thereupon assume responsibility for detailed working drawings. Bids from these fabricators are scrutinized and compared, and the low bids carefully checked before awarding contracts.

Wooden structures. If time permits, it is helpful to provide the millwright with a separate set of drawings of the structure dissociated from the mechanical equipment; this is easily done by tracing from the general detailed plans. If time is short, a set of the general plans can be amended by addition

Table 37. Approximate costs of erecting and equipping mills

Mill, location and year	Nature of process	Daily capacity, tons	Character of building	Total cost of building and equipment	Cost per ton-day, capacity
Tri-state District:					
Media, Webb City, 1915	Rolls, jigs, tables	1500	Wood	$50,000	$34
Typical jig mill, 1916	Rolls, jigs	250	Wood	7,200	30
Typical jig-table mill, 1923	Rolls, jigs, tables	720	Wood	75,000*b*	105
Coarse concentration and flotation:					
Annapolis, Mo., 1922	Jigs, tables, flotation	500	Steel(*a*)	194,760*b*	390
Silver King, Park City, Utah, 1921	Jigs, tables, flotation	300	Steel and concrete	300,000	1000
Tables and flotation:					
Armstead, Talache, Idaho, 1921	Tables and flotation	150	Wood frame	128,154	854
Magma, Superior, Ariz., 1914	Tables and flotation	150	Wood frame	86,420	576
National Copper, Mullan, Idaho, 1914	Tables and flotation	500	Wood frame	162,740	326
Fine crushing, flotation only:					
Betty O'Neal, Lewis, Nev., 1922–3	Ball mills, M. S. flotation	300	Wood frame	200,000	667
Allenby, Princeton, B. C., 1919		2000	Wood frame	1,300,000	650
Shattuck-Arizona, Bisbee, 1917–8	Ball mills, K. & K. flotation	400	Wood frame	294,900	737
Ottawa, Slocan, B. C., 1921	Ball mills, M. S. flotation	50	Wood	30,000	600
Carbon Mt., Ala., 1917	Fine crushing, Callow flotation	240	Wood	45,657*e*	190
Fine crushing, cyanidation:					
United Comstock, Nev., 1921–2		2000	Steel and concrete	1,739,300	870
United Eastern, Oatman, Ariz., 1916		300	Wood frame	200,000	667
Stargo, Morenci, Ariz., 1922		75	Wood frame	77,000*c*	1027
Winnemucca, Nev., 1916		50	Steel	41,850*d*	837
Wright-Hargreaves, Ont., 1919		200	Wood; asbestos covered	161,945	810
Stamps and amalgamation:					
Moore, Jackson, Cal., 1923	20 stamps	100		77,030*f*	770

a Building for 1000-ton capacity; equipped for 500 tons. *b* Excluding power generating plant. *c* Used large proportion of second-hand machinery. *d* Principal steel work second-hand. *e* For soft graphite rock. *f* Including shops and warehouse, but not tailing-disposal plant.

Table 38. Distributed costs of representative mills

Mill	Type	Machinery, F.O.B. factory	Building	Installation	Total	Building and installation per dollar of machinery
Annapolis	Jigs, tables, flotation	$92,365	$102,392*b*	*c*	$194,757	$1.11
Armstead	Tables, flotation	62,497	27,866	$16,707	128,154*a*	1.05
Burro Mountain	Tables, flotation	317,140	198,794	118,695	634,629	1.00
Magma(*d*)	Tables, flotation	50,663	35,756	*c*	86,419	0.71
Winnemucca	Cyanide	25,850	11,756*f*	3,985	41,591	0.61
United Comstock	Cyanide	779,829	732,595	226,883	1,739,307	1.23
United Eastern	Cyanide	110,952	62,079	24,726	197,757	0.78
Media	Jigs, tables	25,410	19,150	5,730	50,290	0.98
Richard	Magnetic separation	72,246	69,334	*c*	141,580	0.96
Carbon Mt.	Flotation	25,715	9,641	5,056	45,660*a*	0.78
Wright-Hargraves	Cyanide	108,618	53,327	*c*	161,945	0.50

a Total includes miscellaneous items, such as freight, engineering fees, supervision, etc., not distributable among the three principal headings.
b Building for twice the capacity of machinery installed. *c* Included under building. *d* Original mill, 1914. *f* Structural steel all second-hand.

of dimensions and such details as are not shown with sufficient clearness for the millwright's use, notably trusses and bins.

14. Methods of cost estimating

A preliminary, approximate idea of the ultimate cost of a complete mill of given type may be gained from the following factors representing in round numbers the range in total cost of erection and installation per ton-day (24-hr.) capacity:

Jig-table mill, Tri-State district (1923), buying electric power....	$105
Coarse concentration, no flotation........	$300– 450
Jigs and/or tables, and flotation...........	800–1200
Fine crushing, all flotation	600– 800
Fine crushing and cyanidation............	1000–1400
Stamps, amalgamation, and vanners........	475– 550

Tri-State mills do not contain fine-crushing machinery; tables (though common) are not universal; flotation has not been generally adopted, owing to the comparatively small proportion of the original feed that is reduced to suitable size; and the usual life of a mill demands cheapness and simplicity of construction.

Table 37 gives examples of mills representing the above types.

Erection and installation. When the prices of all essential machinery have been ascertained, the probable cost of the completed mill can be approximated by the empirical rule that for each $1 in machinery, f.o.b. factory, the cost of erecting the building and installing the equipment will range, under average conditions, from $0.75 to $1 per dollar of machinery cost, running up to $1.25 in exceptional circumstances, such as expensive building materials, inefficient labor, delays, etc.

Table 39. Volume costs of mill buildings

Mill	Type of construction	Cost of mill building only	Enclosed volume of building, cubic feet	Cost of building, per cubic foot, cents
Alamo, Sandon, B. C.	Wood frame	....	461,000	3.458*
Annapolis	Steel	$102,392*a*	716,604	14.3
Armstead	Wood frame	27,866	373,000	7.5
Burro Mountain, 1914–16:				
Crusher building	Steel	35,097	357,424	9.8
Mill & sampling plant	Steel	109,319	1,200,000	9.1
Machine shop	Steel	10,268	108,760	9.4
Carbon Mt.	Wood	9,641	190,476	5.0

Armstead, Talache, Idaho, 1921–2	Wood frame	271,000	....	29.65
		Steel, pounds	Per pound	
Annapolis, Mo., 1922	Steel	320,000	6.47¢ erected and with two coats of paint	

a Remodeling and enlarging old mill.

In one case of an elaborate and complicated ore-dressing and metallurgical plant, requiring unusual provisions for storage and widely extended steel structures, designed for a mine in Utah, the carefully estimated cost of erection and installation was $1.04 for $1 worth of machinery, at factories.

Table 38 gives the relation between the total cost of a few representative mills and the cost of their machinery.

Cost-volume ratios. Under average conditions in United States mining districts, the cost for labor and materials of buildings alone will approximate, per cubic foot of enclosed space: Wooden buildings, 3 to 6¢; steel buildings, 7 to 10¢. Table 39 gives examples.

Erection, labor-cost factors. Based on the QUANTITY OF PRINCIPAL STRUCTURAL MATERIAL required, the cost of erection can be estimated roughly as follows: Wooden structure, $30 to $40 per M bd. ft.; steel structure, 0.75 to 1.5¢ per lb. See Table 40.

Based on TONS OF EQUIPMENT INSTALLED, Table 41 gives the labor cost alone, covering the erection of building and installation of machinery, at representative mills.

Table 41. Labor costs per ton of machinery installed

Mill, year	Machinery installed, tons	Labor costs per ton of machinery			Wages	
		Complete mill building	Installing machinery	Total	Mechanics	Labor
Alamo, Sandon, B. C., 1918	161	$99.30	$62.10	$161.40	$6.75	$5.00
Armstead, Talache, Idaho, 1921	160	70.08	53.70	123.78	5.75	3.75
Magma, Superior, Ariz., 1914	140	85.60	49.00	134.60	4.50	3.00
National, Mullan, Idaho, 1914	265	86.03	44.27	130.30	4.75	3.50
New Haven, Bingham, Utah, 1909	66	25.53	53.47	79.00	5.00	3.00
Imlay, Imlay, Nev., 1909	48	62.38	35.70	98.08	5.00	3.50
Utah Apex, Bingham, Utah, 1909	74	24.60	50.65	75.25	5.00	3.00
Utah Consolidated, Toole, Utah, 1921–2	786	69.30	49.50	118.80	6.50	4.75
Watters, Sheridan, Mont., 1912	81	37.99	40.36	98.35	5.00	3.50

The labor cost for ERECTION OF INDIVIDUAL MACHINES of stated types and sizes is given in Table 42, together with weights and approximate factory prices (1924). Erection costs, of course, will vary with local conditions and wages; hence it should be understood that the figures in Table 42 are intended only for approximate, preliminary estimates.

Table 42. Weights, approximate (1924) prices, and labor cost for erecting the principal items of mill equipment

	Factory weight, pounds	Factory price	Labor cost of erection	Remarks
Crushers, Blake jaw:				
15× 9-in.	12,000	$1,100	$100	All chilled-iron fitted.
20× 10-in.	15,000	1,400	123	
24× 12-in.	25,000	2,200	206	
30× 18-in.	45,000	3,900	387	
36× 24-in.	86,000	8,300	680	
42× 40-in.	135,000	11,200	1172	
Crushers, gyratory (primary):				
5× 18-in. opening (*a*)	5,800	1,060	56	If manganese-steel fitted, add 10 per cent. to prices up to and including 14× 52-in.; on larger sizes, add 15 per cent. (*a*) Two-armed spider.
6× 21-in. opening	8,350	1,215	85	
7× 22-in. opening	14,500	1,750	135	
8× 30-in. opening	21,800	2,210	212	
10× 38-in. opening	32,300	3,040	288	
12× 44-in. opening	47,100	4,120	396	
14× 52-in. opening	68,100	5,550	603	
18× 68-in. opening	101,200	8,375	900	
21× 76-in. opening	156,000	11,600	1450	
Crushers, gyratory (Bull-dog type):				
14× 52-in. opening (*a*)	60,000	5,550	603	Same as preceding. (*a*) Two-armed spider.
18× 68-in. opening	84,500	8,200	850	
21× 76-in. opening	135,000	11,000	1400	
Rolls (belt-driven):				
24× 14-in.	14,000	$1,850	$60	If manganese-steel fitted, add 10 per cent. to prices up to and including 14× 52-in.; on larger sizes, add 15 per cent.
30× 14-in.	18,300	2,500	145	
36× 16-in.	24,500	3,100	280	
42× 16-in.	39,000	4,500	346	
54× 20-in.	102,700	9,600	927	
60× 24-in.	112,000	10,700	1350	
72× 24-in.	186,000	16,750	1990	
Grinders, grate ball-mills:				
3× 3-ft.	10,700	2,000	60	Fitted with Wuest gears, hard-iron liners, but no motor or ball charge. Weight of charge is approximately 25 to 30 per cent. of the weight of mill and liners.
4× 4-ft.	25,500	3,940	130	
5× 4-ft.	31,000	4,800	225	
6× 4-ft.	44,000	5,900	375	
7× 5-ft.	66,000	8,350	660	
8× 6-ft.	95,000	11,500	835	
Grinders, rod-mills:				
2× 4-ft.	8,000	1,600	55	
3× 6-ft.	23,000	4,550	185	
3× 8-ft.	25,000	4,775	220	
4× 8-ft.	44,000	6,600	375	
4× 10-in.	46,500	6,850	430	
5× 10-ft.	88,000	12,500	800	
6× 12-ft.	110,000	19,000	1120	
Grinders, ball-pebble mills:				
5× 10-ft.	34,800	$5,160	$305	Fitted with Wuest gears, hard-iron liners, but no motor or ball charge. Weight of charge is approximately 25 to 30 per cent. of the weight of mill and liners.
5× 12-ft.	37,800	5,280	330	
6× 12-ft.	43,200	6,540	380	
7× 14-ft.	110,000	9,300	970	

Table 42. Weights, approximate (1924) prices, and labor cost for erecting the principal items of mill equipment—*Continued*

		Factory weight, pounds	Factory price	Labor cost of erection	Remarks
Grinders, conical ball mills:					
4.5-ft.×16-in.		11,400	$3,200	$116	
6-ft. ×22-in.		22,100	6,200	208	
7-ft. ×22-in.		28,000	8,300	235	
8-ft. ×22-in.		38,000	10,500	300	
8-ft. ×48-in.		50,000	12,500	375	
Grinders, conical pebble mills:					
6-ft.×22-in.		17,500	4,500	200	
8-ft.×36-in.		32,000	6,000	350	
8-ft.×48-in.		37,000	6,200	400	
Screens, revolving stone:					
30-in.×10-ft.		5,900	850	45	All iron and wood work; no screen covering.
40-in.×10-ft.		8,500	995	70	
48-in.×12-ft.		13,800	1,370	150	
48-in.×16-ft.		15,800	1,550	190	
60-in.×16-ft.		31,900	2,585	390	
Screens, traveling-belt (Callow duplex):					
24-in.×4.5-ft.		3,600	600	65	With screen cloth.
Screens, vibrating (Hum-mer):					
3×5-ft., type 37 (open)		1,270	530	75	Without screen cloth.
Motor-driven generator		600	550		
Screens, impact (Colorado Iron Works Co.):					
3×4-ft.		1,300	350	60	Without screen cloth.
3×6-ft.		1,450	475	75	
Screens, trommels:					
30× 60-in.		2,000	378	75	All iron work; no screen covering or housing.
36× 72-in.		2.400	420	85	
42× 90-in.		3,300	565	115	
48×108-in.		4,000	620	145	
Jigs, Harz type, single:					
Compartments	Sizes, inches				
2	18×36	3,000	575	75	All wood and iron work complete.
2	24×36	3,450	650	90	
3	18×36	4,000	800	115	
3	24×36	4,800	900	140	
4	18×36	5,000	1,025	150	
4	24×36	6,150	1,150	180	
Jigs, Hancock:					
3.5×4.5×25-ft. tank		19,000	4,000	540	As above.
Jigs, Cooley:					
Compartments	Size, inches				
6	48×36	32,000	1,160	500	As above.
7	42×36	32,000	1,175	500	
5	42×36	28,000	905	400	

Table 42. Weights, approximate (1924) prices, and labor cost for erecting the principal items of mill equipment—*Continued*

	Factory weight, pounds	Factory price	Labor cost of erection	Remarks
Tables, Wilfley type:				
No. 6	3,100	$500	$45	Complete, without channel-iron base.
No. 11-D	1,850	450		
Thickeners, Callow-cone:				
8-ft.	650	125	20	
Thickeners, Dorr:				
30×10-ft.	25,000	2,500	300	Wood tank and steel superstructure.
50×12-ft.	52,000	5,800	500	
80×10-ft.	166,000	8,500	1300	As above.

Classifiers, Akins, heavy-duty, submerged:				
45-in.	8,000	1,800	30	With steel tanks and lifting device.
54-in.	14,400	2,850	50	
60-in.	17,500	3,500	75	
78-in.	34,000	4,700	125	
96-in.	44,000	5,800	150	
Classifiers, Allen cone, type 40:				
3.5-ft.	675	400	15	
4.5-ft.	825	450	20	
6-ft.	1,050	550	25	
8-ft.	1,600	700	35	
Classifiers, Richards hindered-settling:				
3-spigot	700	428	15	Iron and woodwork complete.
Filters, vacuum-drum type:				
5-ft. 4-in.×6-ft. = 108 sq. ft. area	8,000	2,475	140	Not including vacuum pump, receiver, etc.
8-ft.×8-ft. = 200 sq. ft. area	12,500	3,590	250	
12-ft.×12-ft. = 432 sq. ft. area	26,000	5,600	520	
Filters, vacuum-disk type:				
2 @ 6-ft. disks = 100 sq. ft. area	6,300	2,100	65	
4 @ 6-ft. disks = 200 sq. ft. area	8,100	3,000	85	As above.
4 @ 8.5-ft. disks = 400 sq. ft. area	14,600	4,800	250	
6 @ 8.5-ft. disks = 600 sq. ft. area	19,000	6,000	325	

* Concrete tank, including excavations and all other items = $31,000.

Table 42. Weights, approximate (1924) prices, and labor cost for erecting the principal items of mill equipment—*Continued*

	Factory weight, pounds	Factory price	Labor cost of erection	Remarks
Filters, pressure, plate-and-frame:				
30 @ 18 × 18-in. sections = 117 sq. ft. area	3,900	$460	$35	
30 @ 24 × 24-in. sections = 212 sq. ft. area	5,800	595	52	
36 @ 30 × 30-in. sections = 400 sq. ft. area	12,300	915	105	
60 @ 36 × 36-in. sections = 977 sq. ft. area	26,415	1,725	130	
Flotation machines, Minerals Separation Co.:				
24-in. @ 16-cell, standard	45,500	10,000	600	Without motor.
24-in. @ 16-cell, sub-aeration	32,500	8,200	450	Without motor.
Flotation machines, Callow pneumatic:				
3 comp., double, 3 × 3-ft. unit	4,050	737	60	Without blower, motor or blower piping.
6 comp., double, 3 × 3-ft. unit	7,800	1,332	100	
9 comp., double, 3 × 3-ft. unit	10,700	1,947	135	
12 comp., double, 3 × 3-ft. unit	13,700	2,564	175	
Feeders, steel-apron type:				
18-in. × 3-ft. 2-in. long	2,000	360	15	Complete with driving mechanism.
30-in. × 4-ft. 2-in. long	2,550	480	30	
48-in. × 5-ft. 2-in. long	3,200	760	40	
Feeders, armored-belt:				
18-in. × 8-ft.	1,235	324	30	As above.
24-in. × 10-ft.	1,870	448	45	
30-in. × 12-ft.	2,460	590	60	
Pumps, centrifugal, water (Gould):				
2-in. = 120 gal. per min. (single suction)	190	95	7.50	
3-in. = 265 gal. per min. (single suction)	280	135	12.50	Single-stage.
4-in. = 470 gal. per min. (single suction)	400	160	20	
6-in. = 1000 gal. per min. (single suction)	600	270	35	
8-in. = 2000 gal. per min. (single suction)	1,000	375	60	
Pumps, triplex, plunger:				
6.5 × 8-in. = 241 gal. per min.	3,700	850	50	Good for 100-ft. lift.
7.5 × 8-in. = 321 gal. per min.	4,600	1,020	65	Good for 100-ft. lift.
9.5 × 8-in. = 501 gal. per min.	5,800	1,190	85	Good for 75-ft. lift.
13 × 8-in. = 975 gal. per min.	10,900	2,210	140	Good for 75-ft. lift.

Table 42. Weights, approximate (1924) prices, and labor cost for erecting the principal items of mill equipment—*Continued*

	Factory weight, pounds	Factory price	Labor cost of erection	Remarks
Pumps, centrifugal, sand (Wilfley):				
2-in. = 175 gal. per min. . .	660	$300	$10	
3-in. = 300 gal. per min. . .	900	400	15	
4-in. = 500 gal. per min. . .	1,650	550	20	
6-in. = 950 gal. per min. . .	2,550	750	30	
8-in. = 2000 gal. per min. . .	4,200	1,200	45	
Compressors and vacuum pumps:				
7.5 × 6-in. = 106 cu. ft. per min. . .	1,400	434	15	
11 × 12-in. = 350 cu. ft. per min. . .	5,400	957	55	Feather valve, belt driven.
15 × 14-in. = 695 cu. ft. per min. . .	8,500	1,520	90	
18 × 16-in. = 1030 cu. ft. per min. . .	12,500	1,891	135	
Blowers, Roots cycloidal:				
No. 2, 600–800 cu. ft. per min.	2,200	463	25	Good for 5 lb. per square inch.
No. 3, 800–1400 cu. ft. per min.	3,300	598	35	
No. 4, 1400–2200 cu. ft. per min.	4,800	764	50	
No. 5, 2200–3000 cu. ft. per min.	8,500	1,089	90	
No. 6, 3000–4600 cu. ft. per min.	14,000	1,596	150	
Elevators, continuous-bucket (Dry):				
9 × 6 × 9-in. buckets, 30-ft. centers.	3,000	405	120	Complete with woodwork.
9 × 6 × 9-in. buckets, 70-ft. centers.	5,200	715	280	
16 × 8 × 11-in. buckets, 30-ft. centers.	4,100	675	135	
16 × 8 × 11-in. buckets, 70-ft. centers.	7,250	1,175	315	
30 × 12 × 13-in. buckets, 30-ft. centers.	9,700	1,650	225	
30 × 12 × 13-in. buckets, 70-ft. centers.	18,000	2,750	525	

Elevators, belt-and-bucket (Wet):

Buckets	Spaced	Centers	Factory weight, pounds	Factory price	Labor cost of erection	Remarks
2 @ 14-in.	18-in.	60-ft.	11,800	2,364	600	All ironwork, belt and buckets, and wood housing.
2 @ 14-in.	18-in.	30-ft.	6,400	1,277	300	
1 @ 16-in.	18-in.	60-ft.	6,300	1,400	450	
1 @ 16-in.	18-in.	30-ft.	3,600	792	225	
1 @ 12-in.	16-in.	60-ft.	4,400	1,018	390	
1 @ 12-in.	16-in.	30-ft.	2,700	551	195	
1 @ 8-in.	12-in.	60-ft.	2,630	700	300	
1 @ 8-in.	12-in.	30-ft.	1,770	418	150	

Table 42. Weights, approximate (1924) prices, and labor cost for erecting the principal items of mill equipment—*Continued*

	Factory weight, pounds	Factory price	Labor cost of erection	Remarks
Tanks, wood, for water, etc.:				
8× 8-ft. = 2,625 gal. (2-in. staves)	1,332	$85	$20	Prices for Douglas fir; for redwood, add approximately 15 per cent.
10×10-ft. = 5,260 gal. (2-in. staves)	2,024	126	25	
12×12-ft. = 9,280 gal. (3-in. staves)	2,914	262	30	
16×12-ft. = 16,000 gal. (3-in. staves)	6,588	389	65	
20×16-ft. = 34,700 gal. (3-in. staves)	11,532	675	120	
30×20-ft. = 100,000 gal. (3-in. staves)	24,980	1,470	250	
40×20-ft. = 178,500 gal. (3-in. staves)	38,213	2,270	380	
Conveyors, belt:				
18-in. belt, 450-ft. centers	15,000	3,834	1,350	All ironwork, belt and rollers; also wood frames and stringers.
18-in. belt, 250-ft. centers	8,100	2,129	750

	Per pound
Complete mill transmission equipment. . . .	16–30¢
Labor erecting.	3– 4¢

Lumber	Weight per M.B.M., pounds	Price per M.B.M.(*a*)	Erection cost per M.B.M.
Oregon fir, common.	3300	\$20	\$25–35
Oregon fir, mine grade.	3300	14	25–35
Redwood.	2750	85	25–35
Reclaimed lumber.	3000	7.50–10	25–35

a Lumber is usually bought at a price of f.o.b. railroad point nearest the place of consumption; freights, while variable, will average about equal to the saw-mill cost of common lumber.

It is intended that the foregoing list shall be used for estimating purposes only. To the factory price of machinery should be added enough to cover (1) freight charges from factory to the railroad point nearest the mill (approximately \$1.50 per 100 lb., or say 2¢ per ton mile, for carload, and twice as much for less than carloads), (2) the cost of hauling from railroad to millsite (say 40¢ per ton-mile for teams, or 20¢ per ton-mile for motor trucks), and (3) the cost of unloading and distributing machinery on the millsite (about \$2.50 per ton),

Excavation that was required at a few mills, and the cost per cubic yard, are given in Table 43.

Table 43. Amount and cost of excavation at typical mills

Mill	Type	Excavation, cubic yards	Cost per cubic yard	Labor wages	Character of material
Magma, Superior, Ariz.	Terraced	1800	$2.47	$2.25	Solid, hard rock.
Imlay, Imlay, Nev.	Terraced	915	0.55	3.50	Medium soft earth.
National, Mullan, Idaho	Terraced	5000	0.88	3.50	Loose rock and earth
Watters, Sheridan, Mont.	Terraced	....	1.50	......	Medium hard rock.
Winnemucca, Nev.	Flat	1155	0.75	......	
Utah Consolidated, Tooele, Utah	Terraced	6000	1.17	4.50	Medium soft earth.

Concrete work, its volume and cost, covering walls, foundations and floors at typical mills, is shown in Table 44.

Table 44. Volume and cost of concrete work at mills

Mill	Type	Total cubic yards	Cost per cubic yard						
			Sand	Rock	Cement	Lumber, etc.	Labor forms	Labor, mixing and placing	Total
Imlay, Imlay, Nev.	Terraced	166	$1.87	*a*	$2.43	.....	$1.40	$3.50	$9.20

Winnemucca, Nev.	Flat	312	.....	.....	.....	.....	......	......	9.50

a Gravel, included with sand. *b* Retaining walls and building foundations. *c* Floors and machinery foundations.

Final estimates are based on completed plans and specifications, previously described (Art. 13). The first step is to prepare an ITEMIZED LIST of all equipment and materials required; much depends on the completeness of this list; nothing should be omitted that will contribute in the least degree to the satisfactory operation of the mill. A few of the items most likely to be overlooked are given in the following list:

Windows. Screen covering. Steel balls. Ore bin, rods and washers. Building rods, bolts, drift spikes and washers. Blower air pipe. Master valves for cells. Main power cable. Main water pipe and cost of digging ditch. Main water tank. Main water pump. Lime bins and feeders (where lime is used). Cranes, hoists, trolleys, chain blocks and beams. Lighting transformers. Fire hydrants. Cable, conduits and connections. Paint and painting. Steam plant and all necessary piping and connections. Electric wiring, material and labor. Equalizing tank and float. Brick (where boiler is used). Fire and water hose. Coal for heating mill during construction. Electric-power poles. Agitator for stock tank. All gear housings. Steel chutes. Bin, launder, chute and spout linings. Steam-pipe covering. Tank for condensation water (where this will not return by gravity). Pump for same. Feed distributors. Belt fasteners. Elevator bolts and washers. Lighting cables, cords, shades and globes. Sampler equipment. Reagent feeders. Reagent storage. Walkways. Stairs. Signal systems. Cleaning up.

Underestimating the cost of a proposed job is invariably due to failure properly to survey and list all the items composing the installation and the work to be done to complete the plant to the point of actual operation. Care in this particular is really more important than precision as to each item, for in the very long list of items almost always needed, individual errors will tend to compensate.

The list should next be SEGREGATED according to the character and source of the materials: ore-dressing equipment (further subdivided as to specialties offered by particular manufacturers); motors and electric appliances; shafting, pulleys, clutches, speed reducers, etc.; belts; piping, valves and fittings; lumber; roofing and siding materials; windows; paints; structural steel-work (not usually necessary to list in detail—see Art. 13); boilers; engines. Bids are then invited from manufacturers of the respective classes, stating weights, prices, and time of delivery. Bids should be scrutinized, not only as to prices and quality, but also to insure that each one covers exactly the amount and kind of material wanted; freight charges to the mill site may affect comparison of factory prices. A convenient form for final presentation is suggested in Fig. 12.

		Coarse crusher & sampler	Concentrator	Tailing disposal	Water system	Stores, shops, etc.	Transportation facilities	Power plant	Totals	
									Cost	Weights
Mach'y & miscellaneous iron work. F. O. B. factory		$	$	$	$	$	$	$	$	lb.
Lumber and/or steel work. Other structural mat'ls.	1									
Labor erecting mach'y etc. Labor erecting bldgs. etc.	2									
Freight & unloading mach'y etc. Freight & unloading build'g mat'l	3									
Excavation Foundations etc.	4									
Electric wiring etc. Piping etc.	5									
Contingent fund @ 5% Engineering	6									
Total of items	7									

Fig. 12. **A form for final cost estimate.**

This generalized tabulation should be accompanied by individual lists relating to each separately-housed department of the plant, following the same itemizing as above, but in more detail; thus, each article of principal equipment should be listed as to weight and price; volumes of excavations and foundations should be stated, with their unit costs; lumber, quantity and unit cost; and similarly as to all other structural materials.

SECTION 24

MATHEMATICS

BY

PERCEY F. SMITH

PROFESSOR OF MATHEMATICS, SHEFFIELD SCIENTIFIC SCHOOL, YALE UNIVERSITY

NOTE—Black-face numbers in parenthesis in the text refer to the bibliography.

ARITHMETIC

1. Approximate computation

Numerical engineering data are subject to errors of various kinds and should be written so that no ambiguity can exist as to the significance of the figures. In the number 0.002953 it would naturally be understood that four SIGNIFICANT FIGURES 2, 9, 5, 3 are intended. In 2,953,000, however, it should be made clear whether the three zeros are in doubt or not. Attention to significant figures is especially important in performing the four fundamental operations of arithmetic, viz., addition, subtraction, multiplication and division. (1)

Addition. A doubtful figure in any of the numbers makes the sum of the column in which it lies doubtful.

Example. In the sum retain figures for those columns only in which all figures are significant. Doubtful figures are indicated by sign x.

2.953xx
0.8942x
0.06483
3.912xx

Subtraction. Reject any column containing a doubtful figure. Ordinary method of subtraction may be replaced with advantage by "SHOP" OR "COMPLEMENTARY" METHOD based upon subtraction as the inverse of addition.

Example. Subtract the sum of 6439 and 954 from 8532. Answer is 1139.

Example illustrates the advantage of the method in working out, in one step, problems involving both addition and subtraction.

8532	$4 + 9 + \underline{9} = 22.$	Set down 9, carry 2.
6439	$7 + 3 + \underline{3} = 13.$	" " 3, " 1.
954	$10 + 4 + \underline{1} = 15.$	" " 1, " 1.
1139	$1 + 6 + \underline{1} = 8.$	" " 1.

Multiplication. It is convenient to arrange the work so that the figures of the multiplier are used from left to right, since doubtful figures are thus displayed prominently to the right of the vertical line. It is unnecessary to write the doubtful figures. The operation may be abbreviated by dropping the right-hand figures of the multiplicand one by one as multiplication is completed by successive figures of the multiplier, making proper allowance for so doing in the products. POSITION OF THE DECIMAL POINT may be determined in the usual way (as many places of decimals in product as in multiplicand and multiplier combined), or, better still, estimated from the given numbers as below.

2,953	
4,128	
11,812	
295	3
59	06
23	624
12,19x	xxx

2,953
4,128
11,812
295
59
24
12,19x

Thus to point off 29.53 × 412.8, think of result as about equal to 30 × 400 = 12,000. Product required contains five figures to left of decimal point. Hence 29.53 × 412.8 = 12,190. Again 0.00002953 × 4128 is best treated by thinking of the multiplier as about 4000, that is, 4 × 1000, the last factor shifting decimal point three places to the right. Hence 0.00002953 × 4128 = 0.1219.

Division. Work may be much abbreviated for numbers with limited significant figures by cutting off one figure of the divisor at each division, instead of adding a doubtful zero from the dividend to the remainder. This method gives rise to no loss in accuracy, and leads quickly to the desired result. Work may be further shortened by omitting the multiples of the divisor, writing down remainders only, using shop method of subtraction.

4128)	12190	(2
	8256	
413)	3934	(9
	3717	
41)	217	(5
	305	
4)	12	(3

4128	12,190	2	$2 \times 8 = 16, + 4 = 20.$	Write down 4, carry 2.
413	3,934	9	$2 \times 2 = 4, + 2 + 3 = 9.$	Write down 3.
41	217	5	$2 \times 1 = 2, + 9 = 11.$	Write down 9, carry 1.
4	12	3	$2 \times 4 = 8, + 1 + 3 = 12.$	Write down 3.

POSITION OF DECIMAL POINT is best determined by estimating the quotient in a manner analogous to that explained for multiplication. Thus in $0.001219 \div 0.4128$, think of the divisor as 4 and point off one less place in the quotient. Answer is 0.002953.

Notation using powers of 10. Engineering tables often employ powers of 10 as factors to bring significant figures into prominence and also to save space.

A power of 10 is indicated by an EXPONENT, which is an integer written at the right and above 10, as 10^2, 10^{-3}. A POSITIVE EXPONENT indicates a product in which 10 appears as a factor a number of times equal to the exponent. Thus $10^2 = 10 \times 10$. A NEGATIVE EXPONENT indicates the reciprocal of (unity divided by) the corresponding positive power. Thus $10^{-3} = 1/10^3 = 1/1000 = 0.001$. A negative power of 10 equals unity written in that place of decimals which corresponds to the numerical value of the exponent. Thus $10^{-1} = 0.1$, $10^{-4} = 0.0001$. The product, or quotient of two powers of 10 is also a power of 10. RULES: $10^a \times 10^b = 10^{a+b}$. $10^a/10^b = 10^{a-b}$. If 2, 9, 5, 3 are the significant figures in 2,953,000, write it 2953×10^3. Also $0.00002953 = 2.953 \times 10^{-5}$. Rule is to write down all significant figures and multiply by the correct power of 10 to take care of decimal point. Multiplication or division of very small or very large numbers is performed conveniently by first writing them with powers of 10 as factors.

Examples. Multiply 0.000002953 by 412,800. Work is, $2.953 \times 10^{-6} \times 4.128 \times 10^5 = 12.19 \times 10^{-1} = 1.219$. *Ans.* Divide 0.001219 by 0.4128. Work is, $12.19 \times 10^{-4} \div 4.128 \times 10^{-1} = 2.953 \times 10^{-3} = 0.002953$. *Ans.*

The above illustrations afford examples of the rule to be followed in DISCARDING SUPERFLUOUS FIGURES, *viz.*: if the first figure of a number discarded is five or more, add a unit to preceding figure.

For greater refinement, when the number rejected is known to be *exactly* five, add a unit to preceding figure when this is odd, leave it unchanged when even. Thus $7.5 \times 75 = 562.5 = 562$ to three figures. $15 \times 22.5 = 337.5 = 338$ to three figures.

Fractions. Product of two fractions is the product of the numerators divided by the product of the denominators. To divide one fraction by another, invert the divisor and multiply.

Ratio and Proportion. Ratio of one number to another is the quotient of the first by second.

Example. Ratio of 7 to 4 is $1\frac{3}{4}$.

Ratio of two numbers is often indicated by the sign : between them. Four numbers are said to be in proportion when the ratio of the first to the second equals the ratio of the third to the fourth.

Example. 2, 3, 8, 12 are in proportion. This is written $2 : 3 = 8 : 12$.

In a proportion, the first and last numbers are called EXTREMES, second and third numbers are called MEANS. A proportion remains true if any of following changes are made: (1) interchange extremes; (2) interchange means; (3) make extremes the means, and means the extremes. In any proportion, product of means equals product of extremes.

Example. Given $2 : 3 = 8 : 12$. (1) $12 : 3 = 8 : 2$; (2) $2 : 8 = 3 : 12$; (3) $3 : 2 = 12 : 8$.

Variation. One number is said to VARY DIRECTLY as another number when their ratio is constant, and to VARY INVERSELY as another number when their product is constant.

Charts to display tables of numerical data. A graphical representation of a table giving corresponding pairs of numbers is made by drawing two lines at right angles from a common point and laying off on one line a scale by which to plot one set of numbers, on the other line an appropriate scale for the second set of numbers. A point on the paper can then be marked for each pair of corresponding numbers, as in Fig. 1.

Example. Chart showing increase of population of United States.

Year	1850	1860	1870	1880	1890	1900	1910
Population in millions	23.2	31.4	38.6	50.2	62.6	76.0	92.0

Scale of years is laid off on horizontal line as marked, and scale of millions in population on vertical line, each division on the latter representing 5,000,000. A point on the vertical line 5 units upward represents population in 1850. For each decade a point is marked directly above the corresponding point for the year at a distance representing population for that year. For example, for 1890, point is 62.6 ÷ 5 = 12.5 divisions upward.

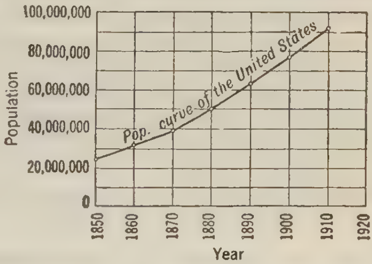

FIG. 1.

2. Errors

A definite number of significant figures is usually implied in a numerical table. The last right-hand digit may be in error, at most, half a unit.

For example, from Table 3, the value for the square root of 7 = 2.646, which means that the exact value lies between 2.6455 and 2.6465, that is, the error lies between − .0005 and + .0005.

In adding numbers taken from a table, errors may accumulate. The last right-hand digit may then be in error several units, and this fact should be noted carefully in any computation. Similar observations apply to other operations of arithmetic. In general the result obtained by computing with numerical tables of say four significant figures cannot be depended upon beyond three significant figures. Hence to reach a desired degree of accuracy it is essential to carry along one extra figure up to the last step.

The ABSOLUTE ERROR in any approximation is the actual difference between the approximate and the exact value. The limits between which the absolute error lies are usually all that is known of its magnitude.

Thus when we take $\sqrt{7} = 2.646$, absolute error lies between -0.0005 and $+0.0005$ and is numerically < 0.0005.

The RELATIVE ERROR is the ratio of absolute error to exact value. Usually in any given case an upper limit only of the relative error is known.

Thus in the preceding illustration, the relative error in $\sqrt{7} = 2.646$ is less than "one part in 2645."

Following are simple theorems on errors.

IN A SUM OR DIFFERENCE, ABSOLUTE ERROR OF THE RESULT IS NOT GREATER THAN THE SUM OF THE ABSOLUTE ERRORS OF THE GIVEN TERMS.

IN A PRODUCT OR QUOTIENT, RELATIVE ERROR OF THE RESULT IS NOT GREATER THAN THE SUM OF THE RELATIVE ERRORS OF THE TERMS (practically).

In calculating, from any formula, a value depending upon given approximate values, limits of the absolute and relative errors may often be found by aid of the Calculus. See Art. 59.

3. Interpolation in Tables

It is often convenient to consult tables for values not directly given, but which may be found by INTERPOLATION BY FIRST DIFFERENCES. This technical phrase is based upon a simple assumption and its application is merely the principle of proportion in arithmetic.

Suppose that in a Table of Square Roots, entries are for numbers of three significant figures, and the square root of a number with four significant figures is wanted to a fair degree of accuracy. Assume that the table gives $\sqrt{211} = 14.525$ and $\sqrt{212} = 14.560$ and that $\sqrt{211.4}$ is desired. Note that the square root increases .035 when the number increases 1 unit. Interpolation is accomplished on the assumption that a fractional increase in the number will cause the same fractional (proportional) increase in the square root. In this case, therefore, the increase of 0.4 (ratio 0.4 : 1) in the number should increase the square root by $.035 \times 0.4 = .014$. Hence $\sqrt{211.4} = 14.525 + .014 = 14.539$. If the tabular square roots have five significant figures, the interpolated result cannot be depended upon to the same degree, but the last figure is in doubt by one unit at most.

4. Logarithms

Explanation of Table 16. The tables are COMMON LOGARITHMS. The number 10 is called the BASE of the system, and the common logarithm of a given number is that power to which 10 must be raised to equal the number. In other words, common logarithms are powers (not necessarily integral) of 10. From the relations $10^{-3} = 0.001$, $10^{-2} = 0.01$, $10^{-1} = 0.1$, $10^0 = 1$, $10^1 = 10$, $10^2 = 100$, $10^3 = 1000$, etc., it is seen that the logarithm of $0.001 = -3$ (written $\log 0.001 = -3$), $\log 0.01 = -2$, $\log 0.1 = -1$, $\log 1 = 0$, $\log 10 = 1$, $\log 100 = 2$, $\log 1000 = 3$, etc.

To find the logarithm of a given number. When the number is greater than 1, the logarithm is positive. To find the decimal part, called MANTISSA, consider the first three significant figures of the number, paying no attention to the position of the decimal point, at present. Table 16 gives the decimal part for any three significant figures, correct to four decimal places.

Thus, the decimal part of log 3.21 = 0.5065; of log 14,000 = 0.1461, of log 98.6 = 0.9939.

If the number has four significant figures and the first figure is 1, the correct decimal part of the logarithm is given immediately in Table 16 (p. 1472), the fourth significant figure being found in the top row.

Thus for log 12.15, decimal part = 0.0846.

When the first figure is 2 or more, pp. 1474–1475 give a CORRECTION for a fourth significant figure at the right of the page. This correction is to be added to the number given in the body of the table.

Thus for log 2634, on the line for 26, the correction under 4 is 7. Hence add 7 to 4200, giving mantissa of log 2634 = 0.4207.

The part of the logarithm preceding the decimal point, called the CHARACTERISTIC, is the number which is one less than the number of digits in the given number preceding the decimal point.

The characteristic of log 26.45 is 1, of log 36,840 is 4, of log 3.862 is 0.

The complete logarithm of a number consists of the characteristic followed by the mantissa.

Thus log 13.15 = 1.1189; log 986.5 = 2.9941; log 3.216 = 0.5073.

If given number has more than four significant figures, cut off the excess figures. (Art. 1.)

When the number is less than 1, the logarithm is negative. To find the mantissa, which is taken positive, follow the same rule as before.

Thus, mantissa of log 0.2652 or log 0.0002652, is same as for 2652.

To the mantissa add the characteristic, which is now *negative* and equal to the number of zeros between the decimal point and the first significant figure of the number, increased by 1.

Thus the characteristic of log 0.2652 = − 1; of log 0.0002652 = − 4. Hence log 0.2652 = 0.4235 − 1(= − 0.5765); log 0.0002652 = 0.4235 − 4(= − 3.5765).

For convenience in calculation, it is customary not to perform the operation of subtracting the characteristic from the mantissa, but to write the characteristic preceding the mantissa, as when positive, and to place a minus sign above it.

For example, write 0.4235–4 as $\bar{4}.4235$. It must not be forgotten, however, that $\bar{4}.4235 = -4 + 0.4235$.

Some computers prefer to add and subtract 10 from a negative logarithm, so as to have a positive number in the units place. In this case − 4 + 0.4235 would be written 6.4235 − 10.

To find a number whose logarithm is given is the inverse of that just described.

Example. To find number whose logarithm = 2.6049. Mantissa is 0.6049. Find in the body of the table the next smaller mantissa. This is 0.6042, corresponding to significant figures 402. A fourth figure must give an added correction 6049 − 6042 = 7, and hence this figure may be either 6 or 7 from the right-hand column. Choosing 6, significant figures are 4026. Characteristic being 2, point off three places. Hence required number is 402.6. If logarithm is $\bar{1}.6049$, corresponding number is 0.4026.

Remark. Above process may lead to an error of at most one unit in last right-hand digit.

Fundamental properties of logarithms. The application of logarithms to computation depends upon the following relations:

(1) $\log (ab) = \log a + \log b$ (3) $\log (a)^n = n \log a$

(2) $\log (a \div b) = \log a - \log b$ (4) $\log \sqrt[n]{a} = (\log a) \div n$

Multiplication by using logarithms. Find the logarithm of each factor and add. The sum is the logarithm of the required product.

Example. Compute $x = 4128 \times 0.00002953$.

$$\begin{aligned} \log 4128 &= 3.6157 \\ \log 0.00002953 &= 0.4702 - 5 \\ \text{Adding, } \log x &= 4.0859 - 5 \text{ or } \bar{1}.0859. \quad \text{Hence } x = 0.1219. \end{aligned}$$

Products of more than two factors are worked out in same manner.

Division by using logarithms. Find the logarithm of the numerator and subtract from it the logarithm of the denominator. The remainder is the logarithm of the quotient. Shop method of subtraction is recommended.

Example. To compute $x = \dfrac{4.128}{0.02953}$

$$\begin{aligned} \log 4.128 &= 0.6157 \\ \log 0.02953 &= \bar{2}.4702 \\ \text{Subtracting, } \log x &= 2.1455 \\ x &= 139.8 \text{ } Ans. \end{aligned}$$

In computing by use of logarithms, negative mantissas must be avoided, since tables give only positive numbers as mantissas. Hence in subtracting a mantissa from a smaller one, first add and subtract 1 from the latter.

Example. Compute $x = \dfrac{0.02953}{0.4128}$

$$\begin{aligned} \log 0.02953 &= -3 + 1.4702 \\ \log 0.4128 &= -1 + 0.6157 \\ \log x &= \bar{2}.8545 \\ x &= 0.07153 \text{ } Ans. \end{aligned}$$

Instead of dividing by a number N, we may multiply by its reciprocal $1/N$. Log of reciprocal of a number is called the COLOGARITHM. Hence in using logarithms in division, we may add the cologarithm of N in place of subtracting log N. This device is useful especially where the divisor is itself a product. Some caution must be observed in using cologarithms. *Colog* N = *log* 1 − *log* N, and *log* 1 = 0. Illustrations following will show the method.

$$\begin{aligned} \log 1 &= 1.0000 - 1 \\ \log 0.2953 &= 0.4702 - 1 \\ \text{Colog } 0.2953 &= 0.5298 \end{aligned} \qquad \begin{aligned} \log 1 &= 2.0000 - 2 \\ \log 41.28 &= 1.6157 \\ \text{Colog } 41.28 &= \bar{2}.3843 \end{aligned}$$

In computation using cologarithms Tables of Cologarithms are useful.

To compute any power of a number using logarithms. Find the logarithm of the number and multiply it by the given power. The product is the logarithm of the desired result.

Example. Compute $x = (0.2953)^5$

$$\begin{aligned} \log 0.2953 &= -1 + 0.4702 \\ \text{Multiply by } & 5 \\ \log x &= -5 + 2.3510 = \bar{3}.3510 \\ x &= 0.002244 \text{ } Ans. \end{aligned}$$

To compute any root of a number using logarithms. Find the logarithm of the given number and divide it by the given index of the root. Quotient is logarithm of desired result. Care is necessary to avoid the introduction of fractional characteristics in the case of roots of numbers less than unity.

Examples. **1.** Compute $x = \sqrt[5]{0.4128}$

$$\begin{aligned} \log 0.4128 &= -1 + 0.6157 \\ \text{(Adding and subtracting 4)} &= -5 + 4.6157 \\ \log x &= \frac{-5 + 4.6157}{5} = \bar{1}.923 \\ x &= 0.8377 \text{ } Ans. \end{aligned}$$

2. Compute $x = 0.073^{0.062}$

$$\begin{aligned} \textit{Solution}, \log x &= 0.062 \log 0.073, \\ \log 0.073 &= -2 + 0.8663 = -1.1337, \\ \log x &= 0.062 \times -1.1337 \\ &= -0.0703 = -1 + 0.9297 \\ x &= 0.8506. \quad Ans. \end{aligned}$$

In computations such as are illustrated above, errors in final logarithms are introduced which may be appreciably greater than the error of the tables. The latter may be assumed to be not greater than half a unit in the fourth decimal place, although it may, by interpolation, be a whole unit at times. Hence, for example, in raising a number to fifth power, an error of five units may occur in the final logarithm and this may even lead to an error, in the number itself, of one unit in the third significant figure. Computation with

four-place tables does not ensure more than three-figure accuracy. Tables with mantissas carried out to five or more places are essential for accuracy to four or more significant figures. Such tables are available in great variety. (2)

5. Slide rule

A logarithmic scale is constructed as follows. On a line (Fig. 2) choose a convenient length OZ. Take OZ as unit of length. Mark at each point on the line the number whose logarithm is the distance of that point from O, *e.g.*, if $OA = \log a$, mark at point A the number a. If any other unit of length is more convenient, the ratio $OA : OZ$ is $\log a$. Point O is marked 1 ($\log 1 = 0$), point Z is marked 10 ($\log 10 = 1$). Integers 2, 3, etc., fall on the scale as marked. Graduations between integers will make it possible to read the number corresponding to any point.

Fig. 2.

Let two such logarithmic scales of the same length be made on cardboard and placed as in Fig. 3 with O_1 on lower scale beneath A on upper scale. Let reading at A be a, at A_1 be a_1. Then reading at B is product aa_1. For $OA + O_1A_1 = OB$. But $OA = \log a$ and $O_1A_1 = \log a_1$. Hence $OB = \log a + \log a_1 = \log aa_1$ (Art. 4). Fig. 3 illustrates multiplication by adding two logarithmic scales. If A_1 comes beyond Z, place scales as in Fig. 4. Then reading at B is product aa_1 divided by 10. For $OA = OB + BA$

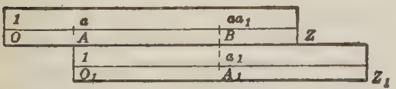

Fig. 3.

Fig. 4.

$= OB + O_1Z_1 - O_1A_1$. Hence $OB = OA + O_1A_1 - O_1Z_1 = \log a + \log a_1 - \log 10 = \log aa_1/10$. Reading at B is the product, as before, save for the position of the decimal point. By writing any number as a product of a number between 1 and 10 by a power of 10, multiplication of any two numbers can be performed as in Fig. 3 or Fig. 4, the position of the decimal point being determined by inspection. In fact, to locate the point on the scale corresponding to any number, consider its significant figures only, and disregard the position of the decimal point.

If readings a and x on the upper scale are directly over readings b and y, respectively, on the lower scale, (Fig. 5), $x/a = y/b$. (For $AX = BY$. But $AX = \log x - \log a = \log x/a$. And $BY = \log y/b$.) Write this equation in the form of a proportion $x : y = a : b$, then for any position of the scales, the readings at two points in a vertical line have a constant ratio.

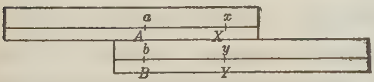

Fig. 5.

Fig. 6.

The logarithmic scale of Fig. 2 is extended to include numbers from 10 to 100 by reproducing the same scale to the right of Z, moving O over to fall on Z,

and replacing the marks 2, 3, 4, etc., by 20, 30, 40, etc. The reason for this lies in the fact that multiplication of a number by 10 increases its logarithm by 1. The scale is now a double logarithmic scale. An immediate advantage of such a scale is that two points on the scale can be marked for any number, according to whether that number is written as the product of a power of 10 by a number between 1 and 10, or between 10 and 100.

Example. 0.0265 can be marked at 2.65, or 26.5.

In the following discussion, assume a pair of double logarithmic scales as in Fig. 6.

Product of two numbers ab. Locate a on upper scale between 1 and 10 and b on lower scale between 1 and 10. Move the lower scale to the right until 1 is in line with a. Product ab is read on the upper scale over b (Fig. 7). Or, locate a on upper scale between 10 and 100, bring 100 on slide in line with a, and read product over b.

Quotient of two numbers a/b. Locate a on upper scale between 10 and 100 and b on lower scale between 1 and 10. Bring b under a. (Fig. 8.) Quotient $x = a/b$ is read on upper scale over 1 on lower scale ($x : 1 = a : b$).

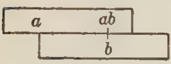

FIG. 7.

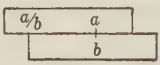

FIG. 8.

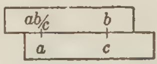

FIG. 9.

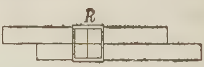

FIG. 10.

Combination of multiplication and division, ab/c. Locate c on lower scale and b on upper scale, and place b over c. (Fig. 9.) Read value $x = ab/c$ on upper scale over a. ($x : a = b : c$.) Or b and c can be marked on one scale and a on the other scale brought over c, when the value of x is read on line with b. ($x : b = a : c$).

To calculate x from

$$x = \frac{abcde\ldots}{pqrs\ldots} = \overset{(1)}{\frac{ab}{p}} \cdot \overset{(2)}{\frac{c}{q}} \cdot \overset{(3)}{\frac{d}{r}} \cdot \overset{(4)}{\frac{e}{s}} \cdot \ldots$$

(1) Place scales so that value of ab/p appears on the upper scale. A RUNNER (R, Fig. 10) is now necessary, consisting of a metal frame with upper and lower edges fitted to the slides so as to move freely back and forth, and carrying a transparent (glass) plate with a visible vertical hair line. Move the runner so that the hair line falls on the reading for ab/p on upper scale. (2) Keeping runner fixed on the upper scale, move the lower scale until q is under the hair line. Value of $\frac{ab}{p} \cdot \frac{c}{q}$ is then on upper scale over c. Move the runner until the hair line falls on this reading. (3) (4), etc.: proceed as in (2). Note that the number of factors in the numerator must be one more than in denominator. Adding the factor 1 a certain number of times may be necessary to accomplish this.

Example. Find value of x when $x = \dfrac{35 \times 144}{1.7 \times 60 \times 6.25}$.

Write $x = \dfrac{35 \times 144}{1.7} \times \dfrac{1}{60} \times \dfrac{1}{6.25}$.

Successive steps are shown in the figures (*1*), (*2*), (*3*), Fig. 11. The result 790 is read over 1 in the position given in the last figure. Decimal point is seen to be after 7. Hence $x = 7.90$ *Ans.*

The ordinary slide rule (Fig. 12) consists of a RULE $ABCD$ with a double logarithmic scale AB (called TOP SCALE) and a single logarithmic scale CD (BOTTOM SCALE) of equal length with AB, a SLIDE F having a double logarithmic scale on its upper edge identical with AB, a single logarithmic scale on the lower edge, congruent with CD, and a RUNNER. (3) The slide has also three scales on the reverse side, to which reference is made later. Multiplication and division are performed as already explained by using scale AB and the upper edge of the slide, or scale CD and the lower edge of the slide. The latter scales are best used, because graduated more finely.

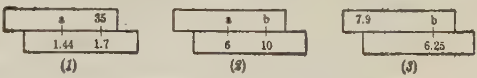

FIG. 11.

Scales are graduated (reference is to the standard 10-in. or 25-cm. rule) as follows: DOUBLE SCALE, each division between 1 and 2 is an increase of .02; between 2 and 5, an increase of .05; between 5 and 10, an increase of 0.1. SINGLE SCALE, each division between 1 and 2 is an increase of 0.01; between 2 and 4, increase of 0.02; between 4 and 10, increase of 0.05. On commercial rules 10, 20, etc., on the top scale are marked 1, 2, etc.

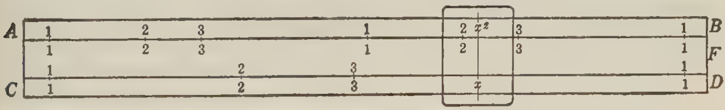

FIG. 12.

Squares and square roots. If the runner is placed in any position, the number under the hair line on AB is the square of the number under the hair line on CD (Fig. 12), proper attention being paid to the decimal point. To find the square root of any number, estimate the first figure of the answer and place the number on AB so that the number under it on CD will begin with the correct figure.

Example. For $\sqrt{18.5}$, first figure is 4. Hence place the runner on 185 on the right-hand half of AB. For $\sqrt{0.0185}$, first figure is 1, hence place the runner on 185 on the left-hand half of AB.

FIG. 13.

Cubes of numbers. To find x^3, set runner over x on CD, and multiply x^2 on AB by x (Fig. 13).

Cube root. Some slide rules are provided with a triple scale on the lower edge of CD of the same length as CD. The hair line on the runner projects over its lower edge, so that cubes of numbers on CD can be read on the triple scale, and cube roots of numbers on the latter can be read on CD.

If the slide is pulled out and turned over, its under side (Fig. 14) shows three scales of the same length as the upper scales. The top scale (marked S) is called S SCALE, the bottom scale (marked T) is called T SCALE, and the middle is called the CENTRAL SCALE. The last is simply the length of the rule subdivided into 500 equal parts, numbered from right to left.

Logarithms of numbers. If the slide is pulled out, inverted, turned end for end and run home, points on scale CD (Fig. 12) will be in line with numbers on the central scale (Fig. 14) thus giving the distances of these points

from C, measured with length $CD = 10$. Hence, numbers on the central scale give mantissas of logarithms of the numbers on the bottom scale.

S-scale (Fig. 14). This is a LOGARITHMIC SINE SCALE, constructed as follows: Length OZ equals length of scales on rule. Mark Z as 90°, and any point A as an angle x satisfying the equation $\log 100 \sin x = 2\ OA/OZ$. Using Table 18 of logarithmic sines (p. 1476) this scale is readily constructed. The point at the left end is 34′, since $\log \sin 34' = -2$. Let the slide be pulled out, inverted, and run back (Fig. 15), so that S-scale comes below scale AB on the rule. A point on the latter is marked a, satisfying $\log a = 2OA/OZ$. Hence, corresponding readings a on AB and x on S-scale satisfy $\sin x = a/100$. Hence, sines of angles between 34′ and 90° may be read off immediately. (Note that $\sin 34' = 0.01$.)

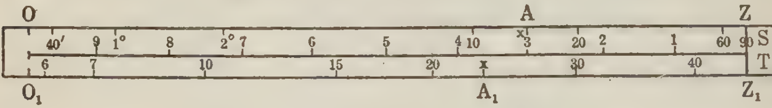

FIG. 14.

T-scale, at bottom of Fig. 14 is a LOGARITHMIC TANGENT SCALE. Point Z_1 is marked 45°, any point A_1 as the angle x for which $\log 10 \tan x = O_1A_1/O_1Z_1$. Let the slide be pulled out, inverted, and run back, as before, the T-scale coming above scale CD on the rule (Fig. 15). Readings x on T-scale and c on CD, in line, satisfy $10 \tan x = c$. Hence, tangents of angles from 5° 43′ to 45° can be read. ($\tan 5° 43' = 0.1$.) For angles greater than 45°, use the formula $\tan (90 - x) = 1/\tan x$. For angles less than 5° 43′, *sine* = *tangent* with sufficient accuracy.

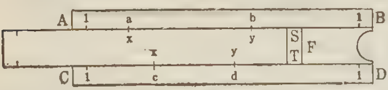

FIG. 15.

Multiplication or division using S-scale or T-scale presents no new principle. For position shown in Fig. 15, the following relations hold: $a : \sin x = b : \sin y$, and $c : \tan x = d : \tan y$. Comparison of these equations with the basic equation $x : y = a : b$ (p. 1351) shows how calculations involving sines or tangents can be made.

Assuming the slide in usual position with number scales in view, turn the rule over and pull out the slide. S- and T-scale will appear as in Fig. 16. A piece of transparent celluloid with hair line H is placed in the end of the rule over the slide as in the figure. It is easy to see that: (1) The reading on the central scale is the logarithm of the number on scale CD under 1 on slide. (2) The reading on the S-scale is the angle whose sine equals the number on the slide beneath 100 on scale AB, divided by 100. (3) The reading on the T-scale is the angle whose tangent equals the number on the slide above 10 on scale CD, divided by 10.

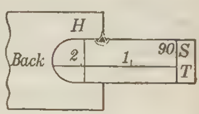

FIG. 16.

For use of the slide rule in trigonometry, see Art. 34.

ALGEBRA

6. Fundamental operations

Notation. The use of letters of the alphabet to represent numbers is the most striking difference between arithmetic and algebra. Different numbers may be represented by the same letter with accents (primes) as a', a'' (read "a-prime," "a-second"), or subscripts as a_1, a_2 (read "a-sub-one,"

"a-sub-two"). When letters occur in a product the multiplication sign ($\times$) is omitted. Thus $3a = 3 \times a$; $2xy = 2 \times x \times y$. The product of a number by itself one or more times is abbreviated by the use of an exponent. Thus $a \times a \times a = a^3$. An EXPONENT is an integer written at the right and above another number to show how many times the latter is to be taken as a factor. Exponent 1 is not expressed. Thus, write a, not a^1. (See also Art. 15.) Letters in algebra stand for negative numbers as well as positive. (4)

Addition and subtraction. In arithmetic, where numbers are always positive, a number may be subtracted from a greater number only. In algebra it is necessary to subtract numbers regardless of their relative magnitudes. To do this, arrange positive and negative numbers on a NUMBER SCALE (Fig. 17).

FIG. 17.

Beginning on a line at a point marked zero, lay off equal distances and mark successive points as indicated, positive numbers to the right, negative to the left. To add the positive number a to the number b begin at b on the number scale and count a spaces to the right. To subtract the positive number a from the number b, begin at b and count off a spaces to the left. Thus, $+2+3=5$; $-5+2=-3$; $-2-3=-5$.

To add a negative number is the same operation as subtracting that number taken with a positive sign. Hence, to add a negative number n to a given number, begin at the latter on the scale and count off n spaces to the left. Subtracting a negative number is the same, in effect, as adding the corresponding positive number. Rule for subtraction is usually stated: Change the sign of the subtrahend and add.

Absolute value of a number is its value without regard to sign. Absolute value of a is written $|a|$. Absolute values of 3, $-1\frac{1}{4}$, -0.51 are 3, $1\frac{1}{4}$, 0.51, respectively. ($|3| = 3$, $|-1\frac{1}{4}| = 1\frac{1}{4}$.)

Sign. To add two or more positive (or negative) numbers, find the sum of their absolute values and prefix to this sum the plus (or minus) sign.

To add a positive and a negative number, find the difference of their absolute values, and prefix to the result the sign of the one which has the greater absolute value.

The product of two numbers having like signs is a positive number and the product of two numbers having unlike signs is a negative number, *e.g.*, $+a \times +b = +ab$, $-a \times +b = -ab$, $+a \times -b = -ab$, $-a \times -b = +ab$. If one factor in a product is zero, the product itself is zero.

The quotient of two numbers having like signs is a positive number, and the quotient of two numbers having unlike signs is a negative number. Division by zero is always excluded.

A MONOMIAL or TERM is an indicated product of two or more numbers. Any factor in a product is called the COEFFICIENT of the product of the other factors, *e.g.*, in $3axy$, $3a$ is coefficient of xy. Terms alike in all respects except coefficients are called SIMILAR. Thus, a^2x, $-3a^2x$, $7a^2x$ are similar terms; also $\sqrt{2}$, $-2\sqrt{2}$, and $3\sqrt{2}$.

To add similar terms, find the algebraic sum of the numerical coefficients and prefix the result to the common part.

Example. $a^2x - 3a^2x + 7a^2x = (1 - 3 + 7)a^2x = 5a^2x$.

To subtract similar terms, change the sign of the subtrahend and add.

A POLYNOMIAL is an expression indicating algebraic addition of two or more dissimilar terms.

Addition of polynomials. Write similar terms in the same column. Find the sum of the terms in each column and add the results.

Example. Add $9ac - bc$, $7ab - 3ac$, and $-12ab + bc$.

$$\begin{array}{rrr} & 9ac & -\ bc \\ 7ab & -\ 3ac & \\ -\ 12ab & & +\ bc \\ \hline \textit{Ans.}\ -\ 5ab & +\ 6ac & \end{array}$$

Use of parentheses. In solving problems it is often necessary to inclose several terms in a parenthesis and such expressions as $(5x - 6y) - [-4x + (4z - y) - 2z]$ occur frequently. A parenthesis preceded by a plus sign may be removed without change in signs of the terms enclosed by that parenthesis. A parenthesis preceded by a minus sign may be removed provided the sign of each term enclosed by that parenthesis is changed. First rewrite the given expression removing the innermost parenthesis, and repeat until all parentheses are removed.

Example. $(5x - 6y) - [-4x + (4z - y) - 2z] = (5x - 6y) - [-4x + 4z - y - 2z] = 5x - 6y + 4x - 4z + y + 2z = 9x - 5y - 2z$. *Ans.*

One or more terms may be placed within a parenthesis preceded by a plus sign without changing the sign of any terms; or preceded by a minus sign provided the sign of each term enclosed is changed.

Example. $a + 2b - c = a + (2b - c) = a - (c - 2b)$.

Multiplication

The factors in a product may be written in any order. Product of a number by itself, a^2, a^4, etc., is called a POWER of that number. The exponent of the product of powers of the same number is the sum of exponents of factors, *e.g.*, $a^m \times a^n = a^{m+n}$.

To multiply two monomials. Obeying the rule of signs for multiplication (see above), write the product of the numerical coefficients followed by all the letters in multiplier and multiplicand, each letter having as its exponent the sum of its exponents in multiplier and multiplicand.

Example. $(3ax)(-2a^2x)(-7ax^3) = 42a^4x^5$.

To multiply a polynomial by a monomial, multiply each term of the polynomial by the monomial and write the algebraic sum of the resulting terms.

Example. Multiply $5x^2 - 2x - 4y$ by $-2xy$.

$$\begin{array}{r} 5x^2 - 2x - 4y \\ -\ 2xy \qquad\qquad \\ \hline -10x^3y + 4x^2y + 8xy^2. \end{array}\quad Ans.$$

To multiply polynomials. Multiply the multiplicand by each term of the multiplier in turn, and add the partial products.

Example. Multiply $x^2 - xy + y^2$ by $x + y$.

Before multiplication, a polynomial should be arranged according to descending powers of one of its letters, that is, so that exponents of that letter in successive terms decrease from left to right. Multiplier and multiplicand should both be arranged with respect to same letter, when possible. DEGREE OF A POLYNOMIAL in any letter equals the greatest exponent of that letter.

$$\begin{array}{lllll} x^2 & - xy & + y^2 & & \\ x & + y & & & \\ \hline x^3 & - x^2y & + xy^2 & & \\ & + x^2y & - xy^2 & + y^3 & \\ \hline x^3 & & & + y^3. & Ans. \end{array}$$

Division

Formula for quotient of powers of a number, $a^m \div a^n = a^{m-n}$ (m greater than n).

To divide one monomial by another divide the numerical coefficient of the dividend by the numerical coefficient of the divisor, following rule of signs in division (see above). Write after this quotient all letters of the dividend except those having the same exponent in divisor and dividend, giving each letter an exponent equal to the difference of exponents in dividend

and divisor. Write any letters in divisor not occurring in dividend under the preceding result as a denominator.

Examples. $\dfrac{-36a^4xb^8}{9a^3xb^7} = -4ab.$ $\dfrac{12ax^3}{-3bx^3} = -4\dfrac{a}{b}.$

To divide a polynomial by a monomial, write down the algebraic sum of the quotients of terms of the polynomial by the monomial.

Example. $\dfrac{15a^2b^2 + 9a^4b^3 - 30a^6b^4}{-3a^2b^2} = -5 - 3a^2b + 10a^4b^2.$ *Ans.*

To divide one polynomial by another. Arrange dividend and divisor according to descending powers of some common letter called the LETTER OF ARRANGEMENT. Divide the first term of the dividend by the first term of the divisor and write the result as the first term of the quotient. Multiply the entire divisor by the first term of the quotient, write the result under the dividend, and subtract. Treat the remainder as a new dividend, and proceed as before, obtaining second term of divisor. Continue until the remainder is zero, or of lower degree than the divisor in the letter of arrangement.

Example. Divide $16x + 12x^3 - 15 - 22x^2$ by $2x - 3$.

$$
\begin{array}{rrrr|ll}
12x^3 & -\,22x^2 & +\,16x & -\,15 & 2x - 3 & \text{Divisor} \\
\cline{5-5}
12x^3 & -\,18x^2 & & & 6x^2 - 2x + 5 & \text{Quotient} \\
\cline{1-2}\cline{5-5}
 & -\,4x^2 & +\,16x & -\,15 & & \\
 & -\,4x^2 & +\,6x & & & \\
\cline{2-4}
 & & 10x & -\,15 & & \\
 & & 10x & -\,15 & & \\
\cline{3-4}
\end{array}
$$

Examples in division should be checked by multiplication, using the formula: dividend = quotient *times* divisor + remainder.

Important special products. $(a + b)(x + y) = ax + ay + bx + by$; $(a + b)(a - b) = a^2 - b^2$; $(a + b)^2 = a^2 + 2ab + b^2$; $(a - b)^2 = a^2 - 2ab + b^2$; $(x + a)(x + b) = x^2 + (a + b)x + ab$; $(ax + b)(cx + d) = acx^2 + (ad + bc)x + bd$; $(a + b)(a^2 - ab + b^2) = a^3 + b^3$; $(a - b)(a^2 + ab + b^2) = a^3 - b^3$. These formulas aid in factoring a polynomial, that is, resolving it into other polynomials of which it is the product. Suggestions that aid in factoring are: (I) look for a monomial factor, and if there is one, separate polynomial into the product consisting of the greatest monomial factor and the quotient of the polynomial by it. (II) From the form of the polynomial factor determine under which of the above types it should be classed and, use the corresponding special-product formula to determine the factors.

Examples. $x^3 - 4x = x(x^2 - 4) = x(x + 2)(x - 2)$.
$9x^2 + 6x + 1 = (3x + 1)^2$. $x^2 - 5x - 6 = (x - 6)(x + 1)$.
$15a^2 + 16ab + 4b^2 = (5a + 2b)(3a + 2b)$.
$x^6 - 64y^{12} = (x^2 - 4y^4)(x^4 + 4x^2y^4 + 16y^8)$.

7. Fractions

The following formulas are important:

$$\frac{a}{b} = \frac{na}{nb} = \frac{a \div n}{b \div n}; \quad +\frac{a}{b} = -\frac{-a}{b} = -\frac{a}{-b}; \quad \frac{a}{c} + \frac{b}{c} = \frac{a + b}{c}.$$

The value of a fraction is unchanged by multiplying numerator and denominator by same number, or by changing the sign of the fraction simul-

taneously with the sign of either numerator or denominator. Sum of fractions with a common denominator equals a fraction with the same denominator and with a numerator equal to the sum of the given numerators. A fraction is in its LOWEST TERMS when no factor except 1 is common to both numerator and denominator.

To reduce a fraction to lowest terms, resolve numerator and denominator into their prime factors, and cancel the factors common to both. (Cancellation is equivalent to dividing numerator and denominator by the product of the common factors.)

Examples in reducing to lowest terms follow:

1. $\dfrac{m^2 - n^2}{m^3 - n^3} = \dfrac{\cancel{(m - n)}(m + n)}{\cancel{(m - n)}(m^2 + mn + n^2)} = \dfrac{m + n}{m^2 + mn + n^2}.$ *Ans.*

2. $\dfrac{a^4 - x^4}{a^4 + 3a^2x^2 + 2x^4} = \dfrac{\cancel{(a^2 + x^2)}(a + x)(a - x)}{\cancel{(a^2 + x^2)}(a^2 + 2x^2)} = \dfrac{a^2 - x^2}{a^2 + 2x^2}.$ *Ans.*

Addition and subtraction

Addition and subtraction of fractions with unlike denominators is accomplished by reduction to a common denominator, as in arithmetic. The LEAST COMMON DENOMINATOR (L.C.D.) of given fractions is the LEAST COMMON MULTIPLE (L.C.M.) of their denominators, namely, that expression having the least number of factors which is divisible by each denominator.

To find L.C.M., resolve each given expression into prime factors. L.C.M. is product of all different prime factors, using each the greatest number of times it occurs in any one expression.

Examples. 1. Find L.C.M. of $6a^2b$, $9ab^2c$, $3ab^3c^3$.

Solution. $6a^2b = 2 \cdot 3 \cdot a^2b$; $9ab^2c = 3^2ab^2c$; $30b^3c^3 = 2 \cdot 3 \cdot 5b^3c^3$.
L.C.M. is $2 \cdot 3^2 \cdot 5 \cdot a^2b^3c^3 = 90a^2b^3c^3$. *Ans.*

2. Find L.C.M. of $ax - ay$, $x^2 + xy$, $x^2 - y^2$.

Solution. $ax - ay = a(x - y)$; $x^2 + xy = x(x + y)$; $x^2 - y^2 = (x + y)(x - y)$.
L.C.M. is $ax(x - y)(x + y) = ax^3 - axy^2$. *Ans.*

To find the algebraic sum of two or more fractions (in their lowest terms). Reduce the given fractions to equivalent fractions having the L.C.D. Write in succession over L.C.D. the numerators of equivalent fractions, inclosing each numerator in a parenthesis preceded by the sign of the corresponding fraction. In this fraction, remove parentheses, combine like terms, and reduce the result to lowest terms, if necessary.

Example. 1. Reduce $\dfrac{4x^2 - 5}{3x^2} - \dfrac{2 - 3x}{2x} + \dfrac{3x - 7}{5x^3}.$

Solution. L.C.D. $= 30x^3$.
Hence,

$$\frac{(4x^2 - 5)10x}{3x^2 \cdot 10x} - \frac{(2 - 3x)15x^2}{2x \cdot 15x^2} + \frac{(3x - 7)6}{5x^3 \cdot 6} = \frac{10x(4x^2 - 5) - 15x^2(2 - 3x) + 6(3x - 7)}{30x^3}$$

$$= \frac{85x^3 - 30x^2 - 32x - 42}{30x^3}. \quad \textit{Ans.}$$

2. Reduce $\dfrac{2}{x^2 - 7x} - \dfrac{3}{x} + \dfrac{3}{x - 7}.$

Solution. L.C.D. $= x(x - 7)$.

Hence, $\dfrac{2}{x(x - 7)} - \dfrac{3(x - 7)}{x(x - 7)} + \dfrac{3x}{x(x - 7)} = \dfrac{2 - 3(x - 7) + 3x}{x(x - 7)} = \dfrac{23}{x^2 - 7x}.$ *Ans.*

Multiplication of fractions follows the formula $\frac{a}{b} \times \frac{c}{d} = \frac{ac}{bd}$. Numerators and denominators must be resolved into prime factors and the common factors in the products of numerators and of denominators canceled.

Division of fractions. Invert divisor, and proceed as in multiplication.

Example. Reduce $\frac{x^2 + x - 30}{x^2 + 5x - 6} \div \frac{x^2 - 25}{x^2 - 6x + 5}$.

Solution. Factoring,

$$\frac{\cancel{(x+6)}(x-5)}{\cancel{(x+6)}(x-1)} \div \frac{\cancel{(x-5)}(x+5)}{\cancel{(x-5)}(x-1)} = \frac{(x-5)\cancel{(x-1)}}{\cancel{(x-1)}(x+5)} = \frac{x-5}{x+5}. \quad \textit{Ans.}$$

8. Equations

An equation is a statement of equality between number symbols. In algebra, equations contain certain letters, called UNKNOWNS, and it is desired to find numerical values to be assigned to these unknowns such that the equations are satisfied. This process is called SOLVING THE EQUATIONS. The following statements suggest methods for simple equations. If the same number is added to, or subtracted from, each member of an equation, the result is an equation. If each member of an equation is multiplied or divided by the same number, the result is an equation.

Example. Solve the equation $5x - 8 = 2x + 19$ for x.

Solution. Subtracting $2x$ from each member, $3x - 8 = 19$.
Adding 8 to each member, $3x = 27$.
Dividing each member by 3, $x = 9$. *Ans.*

Check. Substituting $x = 9$ in given equation, $5(9) - 8 = 2(9) + 19$, or $37 = 37$.

The first of the preceding statements is replaced by the RULE FOR TRANSPOSITION of terms from one member to the other, which is: A term may be omitted from one member of an equation, provided the same term with sign changed is written in the other member.

Equations often contain other letters beside the unknowns. In solving such equations, called LITERAL EQUATIONS, answers will usually involve the other letters. Unknowns are generally denoted by letters near the end of the alphabet, as x and y. Equations containing fractions are CLEARED OF FRACTIONS when both members are multiplied by the L.C.M. of the denominators of the fractions.

Example. Solve $ax + 2ab = 2a^2 + bx$.

Solution. Transposing

$$ax - bx = 2a^2 - 2ab$$

Factoring first member,

$$(a - b)x = 2a^2 - 2ab.$$

$$\therefore x = \frac{2a^2 - 2ab}{a - b} = 2a. \quad \textit{Ans.}$$

Check. $a \cdot 2a + 2ab = 2a^2 + b \cdot 2a,$
$2a^2 + 2ab = 2a^2 + 2ab$

A LINEAR EQUATION (OR EQUATION OF FIRST DEGREE) is one in which the unknown does not appear in any denominator, and its first power only is involved. A QUADRATIC EQUATION (OR EQUATION OF SECOND DEGREE) is one which, when cleared of fractions, involves the square of the unknown but no higher power.

Many quadratic equations can be solved immediately by factoring. Transpose all terms to the first member. Factor this, set each factor containing the unknown equal to zero, and solve the resulting equations.

Algebraic methods are widely used for solving problems expressible in form of equations.

Example. An automobile makes a run of 120 miles. The driver on the return route increases the speed by 5 mi. per hr., and reduces the time by 4 hr. Find speed going and returning.

Solution. Let x = speed (mi. per hr.) going, then $x + 5$ = speed (mi. per hr.) returning. Also $\frac{120}{x}$ = time (hr.) going, and $\frac{120}{x+5}$ = time (hr.) returning. $\therefore \frac{120}{x} = \frac{120}{x+5} + 4$.

L.C.M. of denominators is $x(x + 5)$. Multiply both members by this

$$120(x + 5) = 120x + 4x(x + 5).$$

Transposing and reducing, $x^2 + 5x - 150 = 0$. Factoring $(x + 15)(x - 10) = 0$. $\therefore x + 15 = 0$, or $x = -15$. $x - 10 = 0$, or $x = 10$.

Disregarding the negative answer, speed going is 10 mi. per hr.; speed returning, 15 mi. per hr. *Ans.*

9. Simultaneous linear equations

System of two equations with two unknowns. The typical form to which such a system can be reduced is $a_1x + b_1y = c_1$, $a_2x + b_2y = c_2$. The system may be solved by (a) ADDITION and SUBTRACTION, or by (b) SUBSTITUTION. (For determinants, see Art. 14.) In either case, the principle used is to obtain from the given equations one equation containing only one of the unknowns (ELIMINATION of the other unknown).

Equations of a system are INCOMPATIBLE when there is no common solution; DEPENDENT when there is an indeterminate number of solutions. Thus $x + 2y = 4$, and $x + 2y = 8$ are obviously incompatible, while $x + 2y = 4$, and $2x + 4y = 8$ are dependent, the second arising from the first by using the multiplier 2.

Example. Solve the simultaneous equations: (1) $5x - 3y = -1$, (2) $x + 2y = 5$.

(a) *Solution by addition and subtraction*: Eliminate x by multiplying members of (2) by 5:

$$\begin{array}{ll} (1) & 5x - 3y = -1 \\ (3) & \underline{5x + 10y = 25} \end{array}$$

Subtract: $-13y = -26$. $\therefore y = 2$.

Substitute in (2): $x + 4 = 5$. $\therefore x = 1$.

(b) *Solution by substitution*: Solve (2) for x, giving $x = 5 - 2y$. Substitute in (1): $5(5 - 2y) - 3y = 1$. $\therefore -13y = -26$. $y = 2$.

System of three equations with three unknowns.

Example. Solve the simultaneous system

(1) $4x - 2y + z = 9$, (2) $3x + y + 2z = 13$, (3) $2x + 3y - 3z = -2$.

Solution. Eliminate y from (1) and (2), and (2) and (3).

$$\begin{array}{llll} (1) & 4x - 2y + z = 9. & (3) & 2x + 3y - 3z = -2 \\ (2)\ \textit{times}\ 2 & \underline{6x + 2y + 4z = 26} & (2)\ \textit{times}\ 3 & \underline{9x + 3y + 6z = 39} \\ (4)\ \text{Add} & 10x + 5z = 35 & (5)\ \text{Subtract,} & -7x - 9z = -41 \end{array}$$

Solving (4) and (5) for x and z, $x = 2$, $z = 3$. Substituting in (1), $y = 1$.

Check. Substitute values found in (2) and (3).

A system of any number of linear equations in an equal number of unknowns may be solved in a similar manner by eliminating one variable from the system, thus reducing number of equations and number of variables by one, then another variable from the new system, etc. As in the case of two variables, incompatible or dependent equations may be contained in the given system or reduced system.

10. Quadratic equations

Typical form for quadratic equations is $ax^2 + bx + c = 0$. The equation has two solutions or ROOTS, x_1 and x_2.

Solution by formula.

$$x_1 = (-b + \sqrt{b^2 - 4ac})/2a, \; x_2 = (-b - \sqrt{b^2 - 4ac})/2a.$$

Sum of roots, $x_1 + x_2 = -b/a$. **Product of roots,** $x_1x_2 = c/a$.

Solution of a quadratic equation may lead to roots which are IMAGINARY NUMBERS, that is, numbers involving the square root of a negative number, *e.g.*, $3 + \sqrt{-11}$. Numbers not imaginary are called REAL NUMBERS. The equation has EQUAL ROOTS when $b^2 - 4ac = 0$; IMAGINARY ROOTS when $b^2 - 4ac < 0$. (See p. 1364.)

Solution by factoring. See Art. 6. A formula sometimes useful in factoring is

$$ax^2 + bx + c = a\left(x + \frac{b - \sqrt{b^2 - 4ac}}{2a}\right)\left(x + \frac{b + \sqrt{b^2 - 4ac}}{2a}\right).$$

Solution by completing the square. Transpose terms containing x to first member and other terms to second member. Divide both members by the coefficient of x^2. Add to both members the square of half the coefficient of x, thereby making the first member a perfect square. Rewrite the equation, expressing the first member as a square, and reduce the second member to its simplest form. Extract the square root of both members, writing the sign $\pm$ (plus and minus) before the square root of the second member, thus obtaining two linear equations.

Example. Solve $2x^2 - 9x + 4 = 0$. Successive steps give the equations, $2x^2 - 9x = -4$; $x^2 - \frac{9}{2}x = -2$; $x^2 - \frac{9}{2}x + (\frac{9}{4})^2 = -2 + (\frac{9}{4})^2$; $(x - \frac{9}{4})^2 = \frac{49}{16}$; $\therefore x - \frac{9}{4} = \pm \frac{7}{4}$.
Hence, $x = \frac{9}{4} + \frac{7}{4} = 4$, and $x = \frac{9}{4} - \frac{7}{4} = \frac{1}{2}$. *Ans.*
Check by substituting $x = 4$ and $x = \frac{1}{2}$ in the given equation.

System involving a linear and a quadratic equation, two unknowns. A quadratic equation in two unknowns contains one or more terms of the second degree (such as x^2, xy, y^2), but no term of higher degree in the unknowns. (The DEGREE OF A TERM IN x AND y is the sum of the exponents of these letters.)

To solve a system of the kind named, solve the linear equation for one unknown in terms of the other, substitute this value in the quadratic equation, and solve the resulting quadratic equation in one unknown. Substitute each root of this equation in the linear equation to find the corresponding value of the other unknown.

Example. Solve the system (1) $x^2 + 3xy = 25$, (2) $2x + y = 10$. From (2), $y = 10 - 2x$. Substituting in (1), $x^2 + 3x(10 - 2x) = 25$; reducing, $x^2 - 6x + 5 = 0$. Solving, $x = 1$ and 5. Substitute in (2): $y = 8$ and 0. Check. Substitute in (1) corresponding pairs of solutions $x = 1$, $y = 8$, and $x = 5$, $y = 0$.

11. Graphs of equations

Definitions. Draw two lines at right angles to each other, as $X'OX$, called X-AXIS, and $Y'OY$, called Y-AXIS, as in Fig. 18. Construct a NUMBER SCALE (Art. 6) on each line, point O being marked zero on both. Length of a division on the scales, called UNIT OF LENGTH, is (usually) the same on both axes. From any point (not on either axis) draw lines parallel to each axis, terminating in an axis. Distances parallel to X-axis are called ABSCISSAS, and are positive when to the right of Y-axis, negative on the left. Distances parallel to Y-axis and called ORDINATES, and are positive when above the X-axis, negative when below. For any point, the two distances are called CO-ORDINATES of the point, and their lengths are written in parenthesis, as (3, −4), the abscissa first. Axes divide the plane into four QUADRANTS, as marked in the figure. Signs of co-ordinates for points in different quadrants

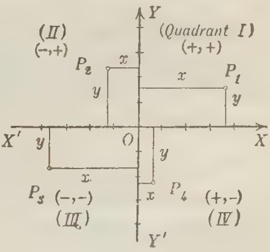

FIG. 18.

are indicated in parentheses. Every point (including those on axes) corresponds to a pair of real numbers, namely, its co-ordinates. Every pair of real numbers will determine a point, of which the given numbers are the co-ordinates. The point O, whose co-ordinates are (0, 0) is called the ORIGIN. Locating points with given co-ordinates is called PLOTTING POINTS. Axes are called AXES OF CO-ORDINATES, X-axis is the AXIS OF ABSCISSAS, and Y-axis the AXIS OF ORDINATES. (**5**)

Graph of linear equation in two unknowns. An indefinite number of corresponding pairs of values of x and y can be found to satisfy a linear equation in these unknowns. It can be shown that all such points lie on a straight line (See Art. 46). This line is called the GRAPH OF THE EQUATION. The graph of a linear equation in one unknown, as $x = 3$, is a straight line parallel to the Y-axis, 3 units to the right. Graph of $y = -1$ is straight line parallel to X-axis, 1 unit below it.

Example. Draw graph of $2x - 3y + 6 = 0$.
Solution. Solve for y, $y = \frac{2}{3}x + 2$. Assume values for x, calculate corresponding values of y, arranging in table. Plot points, and draw line through them (Fig. 19).

x	y	x	y
0	2	0	2
1	$2\frac{2}{3}$	-1	$1\frac{1}{3}$
2	$3\frac{1}{3}$	-2	$\frac{2}{3}$
3	4	-3	0
etc.	etc.	etc.	etc.

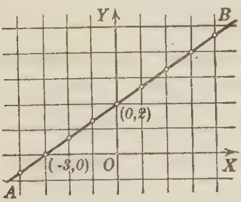

FIG. 19.

Graphical solution of system of two linear equations, two unknowns. Plot straight lines which are graphs of the given equations. Co-ordinates of the point of intersection are numbers satisfying both equations, hence the solution.

Graph of a quadratic equation. Given a quadratic equation in one unknown with the second member zero, as $ax^2 + bx + c = 0$, all points whose co-ordinates satisfy $y = ax^2 + bx + c$ lie on a curve (a parabola, see Art. 49), called the GRAPH OF QUADRATIC EQUATION. Real roots of a quadratic equation are abscissas of points at which the graph meets the X-axis. ($y = 0$ for these values of x.) Graph of $ax^2 + bx + c = 0$ will cross, touch, or not meet the X-axis according as the roots are real and unequal, equal, or imaginary.

Fig. 20 shows graph of $x^2 - 2x - 3 = 0$. Roots are 3, − 1.

Graphical solution of a quadratic equation. Write the equation in the form $x^2 = ax + b$. Plot the parabola $y = x^2$, and the straight line $y = ax + b$. Abscissas of points of intersection are the required roots.

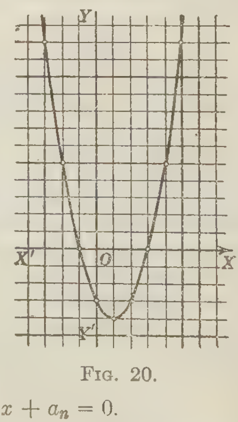

FIG. 20.

12. Graph of numerical equation of higher degree (than 2) in one unknown

Location of real roots. Typical form of equation of degree n is

$$(A) \qquad a_0x^n + a_1x^{n-1} + a_2x^{n-1} + \dots . a_{n-1}x + a_n = 0.$$

(Reference is made below to this equation as "equation (A)".) It is assumed hereafter that all terms in an equation have been transposed to the first

member. (5) The curve passing through all points whose co-ordinates satisfy the equation obtained by setting y equal to the first member is called the graph of the equation. The abscissa of any point of intersection of the graph and the X-axis is a real root of the equation ($y = 0$). Plotting the graph will often show the existence of one or more real roots, either integral, or lying between successive integers. For a short method of calculating ordinates, see Synthetic division, Art. 13.

Art. 13. Theorems on equations of degree n

Remainder theorem. When a polynomial in x is divided by $x - (r)$, the remainder obtained is the value of the polynomial resulting when r is substituted for x.

Example. When $3x^3 + 4x^2 - 6x + 5$ is actually divided by $x - 2$, the remainder is 33. For $x = 2$, $3.2^3 + 4.2^2 - 6.2 + 5 = 24 + 16 - 12 + 5 = 33 =$ remainder.

Linear factors and roots. A number r is a root of an equation with all terms transposed to the first member when and only when that member is exactly divisible by x minus the number r, *i.e.*, by $(x - r)$. Roots of numerical equations of degree greater than two may often be found by trial. The remainder theorem states, for example, that trial of 3 as a root of $3x^3 + 6x^2 - 8x + 4 = 0$ may be made by dividing the first member by $x - 3$, instead of substituting $x = 3$. Application of the theorem is made easy because of an abbreviated method of dividing a polynomial by a linear factor of the form $x - (r)$. The method is called SYNTHETIC DIVISION. To divide a polynomial in x by a linear factor of the form $x - (r)$, write down the successive coefficients a_0, a_1, a_2, etc., of descending powers of the polynomial in a horizontal line from left to right. Bring down the first coefficient a_0. Multiply a_0 by r and add the product to the second coefficient a_1. Multiply the sum $(a_0r + a_1)$ so obtained by r, and add to the third coefficient a_2. Continuing this process, the last sum will be the remainder, and the preceding sums from left to right the successive coefficients of descending powers of the quotient.

Explanation. The number $2(=r)$ is bracketed to the right of the line of coefficients. The first coefficient 3 is written down below the original ones. Multiply it by 2 and add the product $(3 \times 2 = 6)$ to the second coefficient 4. Multiply sum $(4 + 6 = 10)$ by 2, and add the product $(10 \times 2 = 20)$ to the third coefficient -6. Continuing, the last sum 33 is the remainder, and the preceding sums 3, 10, and 14, are successive coefficients of the quotient $3x^2 + 10x + 14$.

Example. Divide $3x^3 + 4x^2 - 6x + 5$ by $x - 2$.

Solution

$$\begin{array}{l} 3 + 4 - 6 + 5 \,\underline{|\,2} \\ + 6 + 20 + 28 \\ \hline \underbrace{3 + 10 + 14} + 33 = \text{Remainder} \end{array}$$

Coefficients of quotient, $3x^2 + 10x + 14$.

Note. If powers of x are missing in the given polynomial, their places must be supplied to zero coefficients. Thus to divide $x^3 + 8$ by $x + 2$, write $x^3 + 8 = x^3 + 0 \cdot x^2 + 0 \cdot x + 8$, and $x + 2 = x - (-2)$. Hence the work is

$$\begin{array}{l} 1 \quad\; 0 \quad\; 0 + 8 \,\underline{|\,-2} \\ - 2 + 4 - 8 \\ \hline 1 - 2 + 4 \quad 0 \end{array}$$

$\therefore x^3 + 8 = (x^2 - 2x + 4)(x + 2)$.

Synthetic division should be used to calculate the ordinates of a graph.

Example above shows that the graph of $3x^3 + 4x^2 - 6x + 5 = 0$ passes through (2, 33) the value 33 being found by synthetic division.

Number of linear factors and roots. An equation of degree n has precisely n linear factors of the form $x - r$. Since each factor corresponds to a root, an equation of degree n has n roots. A linear factor may be repeated (twice,

three times, etc.), in which case the equation has a MULTIPLE ROOT (DOUBLE ROOT, TRIPLE ROOT, etc.). If $r_1, r_2, \ldots, r_n$ are roots of the equation (A), (page 1362) it may be written

$$(B) \qquad a_0(x - r_1)(x - r_2) \ldots (x - r_n) = 0.$$

Relations between coefficients and roots. In an equation in which the coefficient of the highest power is unity, the coefficient of the second term with sign changed equals the sum of all the roots; the coefficient of the third term equals the sum of all products formed from two of the roots at a time; the coefficient of the fourth term with sign changed equals the sum of all the products formed from three of the roots at a time; etc. When the degree is even, the last coefficient equals the product of all roots; when odd, the last coefficient, with sign changed, equals the product of all roots.

Imaginary roots. If the imaginary number $a + b\sqrt{-1}$ (a and b being real numbers) is a root of an equation with real coefficients, $a - b\sqrt{-1}$ is a root also. Imaginary roots occur only in conjugate pairs in equations with real coefficients.

The imaginary numbers $a + b\sqrt{-1}$, $a - b\sqrt{-1}$ are called CONJUGATE IMAGINARIES, and differ only in sign of the imaginary part. The corresponding factors are $x - (a + b\sqrt{-1})$, and $x - (a - b\sqrt{-1})$. Their product is $x^2 - 2ax + a^2 + b^2$, and this product is a REAL QUADRATIC FACTOR of the equation. Number $a + b\sqrt{-1}$ ($a \neq 0$) is called, more exactly, a COMPLEX NUMBER (Art. 21).

Integral roots. Every integral root of an equation with integral coefficients is a factor of the last term. By this theorem all possible integral roots are found in advance by factoring the last term.

Solution of numerical equation of higher degree by trial. Clear the equation of fractional coefficients. If one integral root can be found, a linear factor is known, and the quotient is quickly found by synthetic division. The remaining roots are roots of the equation obtained by setting the quotient equal to zero, an equation of degree less by one than original. Factor last term. Since $+1$ and -1 are always factors, each should be tried for a root (by inspection). If either is a root, remove corresponding factor $(x - 1)$ or $(x + 1)$. Other factors of last term should be tried by Synthetic division. When enough factors have been removed to reduce the remaining quotient to a quadratic, this may be solved as usual.

Example. Solve $x^4 - x^3 - 9x^2 + 11x + 6 = 0$ by trial. Try $+1$ and -1. Substituting these values in turn, neither is a root. Other factors of 6 are ± 2, ± 3, ± 6. Trying $+2$, it turns out to be a root.

The equation now may be written

$$(x - 2)(x^3 + x^2 - 7x - 3) = 0.$$

The second factor shows that only $+3$ or -3 should be tried. Try -3. It is a root. Equation now is $(x-2)(x+3)(x^2-2x-1) = 0$. Solving for roots of quadratic factor, they are found to be $1 \pm \sqrt{2}$. Hence the roots of the given equation are $2, -3, 1+\sqrt{2}, 1-\sqrt{2}$.

$$\begin{array}{rrrrrl} 1 & -1 & -9 & +11 & +6 & \lfloor 2 \\ & +2 & +2 & -14 & -6 & \\ \hline 1 & +1 & -7 & -3 & 0 & \end{array}$$

$$\begin{array}{rrrrl} 1 & +1 & -7 & -3 & \lfloor -3 \\ & -3 & +6 & +3 & \\ \hline 1 & -2 & -1 & 0 & \end{array}$$

Fractional roots. Equations of degree higher than two with no integral roots cannot be solved by the method just explained. Such equations may, however, have fractional roots. When the coefficient of the highest power is not 1, divide by it. The remaining coefficients may then be reduced to integers as follows. After dividing the equation by the coefficient of the highest power, write in any missing powers of x with zero coefficients. Insert factors $m, m^2, m^3 \ldots$ in second, third, fourth, $\ldots$ terms. Choose for m

the smallest integer which will reduce all coefficients to integers. Roots of this transformed equation will be m-times the roots of the original equation. This transformation is called MULTIPLYING THE ROOTS BY m. Find integral roots of transformed equation by trial and divide each by the value of m. Quotients are roots of original equation.

Example. Solve $36x^4 - 55x^2 - 35x - 6 = 0$. Divide by 36, and write $x^4 + 0 \cdot x^3 - \frac{55x}{36} - \frac{35x}{36} - \frac{1}{6} = 0$. Putting in powers of m, $x^4 + 0 \cdot mx^3 - \frac{55}{36}m^2x^2 - \frac{35}{36}m^3x - \frac{1}{6}m^4 = 0$. Choose $m = 6$, giving $x^4 + 0 \cdot x^3 - 55x^2 - 210x - 216 = 0$. Roots of this equation are $-2, -3, -4, 9$.

Hence roots of original equation are

$$-\tfrac{1}{3}, \quad -\tfrac{1}{2}, \quad -\tfrac{2}{3}, \quad \tfrac{3}{2}. \quad Ans.$$

All possible fractional roots may be found in this way because of the theorem: An equation in which the coefficient of the highest power is unity, and other coefficients integral, cannot have a fractional root.

Changing signs of roots. If the signs of alternate terms ($m = -1$) are changed, the transformed and original equations have roots differing only in sign.

Incommensurable roots

Real roots that are neither integral nor fractional may be computed to any number of decimal places by various methods. The existence of real roots is indicated by the LOCATION THEOREM: Let two real numbers a and b be substituted for x in the first member of the equation; if the resulting numerical values differ in sign, an odd number of roots will lie between $x = a$ and $x = b$. The graph of the equation must join points on opposite sides of the x-axis, hence must cross this axis an odd number of times. (See Art. 11.) When a and b are successive integers, only one root will, as a rule, lie between them.

Example. In equation $x^3 - 6x^2 + 3x + 5 = 0$, putting y = the first member, corresponding values of x and y are as shown in table. (Values of y are found by synthetic division.) One root lies between -1 and 0, one between 1 and 2, and one between 5 and 6. These roots are incommensurable, since there are no fractional nor integral roots.

x	y
-1	-5
0	$+5$
$+1$	$+3$
$+2$	-5
$+5$	-5
$+6$	23

Horner's method. Assume a positive root located between $x = h$ and $x = h + 1$, where h is an integer not zero. Substitute $x = y + h$ in the equation. Roots of this new equation in y will be roots of the original equation diminished by h. (Since $y = x - h$.) Hence the equation in y must have a root between 0 and 1. The first significant figure of this root (in first place of decimals) will be the second figure of the root of the original equation. If this root of the equation in y is located between $y = k$ and $y = k + 0.1$ (k being an integer in the tenth's place), put $y = z + k$. The equation in z will have a root between 0 and 0.1, and its first significant figure in the hundredth's place will be

Example. Diminish the roots of $x^3 - 6x^2 + 3x + 5 = 0$ by 1.

$$\begin{array}{l}
1 - 6 + 3 + 5 \;\underline{|\,1} \\
\underline{\quad + 1 - 5 - 2} \\
1 - 5 - 2(+3) = \text{1st remainder} \\
\underline{\quad + 1 - 4} \\
1 - 4(-6) = \text{2nd remainder} \\
\underline{\quad + 1} \\
1(-3) = \text{3rd remainder}
\end{array}$$

The transformed equation is $x^3 - 3x^2 - 6x + 3 = 0$. (The example shows compact arrangement of the work by synthetic division.)

the third figure of the root sought of the equation in x. This outline of HORNER'S METHOD FOR POSITIVE ROOTS indicates that a suite of equations (A), (B), (C), . . . is obtained by transformations which diminish the roots by a given number.

To diminish the roots of an equation by any given number h. Divide the given equation by $x - h$. The remainder is the last coefficient in the transformed equation. Divide the quotient obtained by $x - h$. The remainder is the coefficient of the next to last term in the transformed equation. Continue this process, the last remainder being the coefficient of the second term in the new equation. The coefficients of the highest powers are the same in the original and transformed equations.

Negative roots. Write down an equation with roots differing only in sign from those of the given equation (p. 1365), and calculate the positive roots of this equation. In locating roots greater than 10 and less than 100, it suffices to use the intervals 10, 20, 30, etc. To avoid diminishing by a number greater than 10, multiply roots by 0.1 (p. 1364). In the transformed equation, the root desired will lie between successive integers. For a root greater than 100, multiply roots by 0.01. In reduction by a figure in the tenth's place, decimals can be avoided by first multiplying roots by 10. Similarly for a figure in any succeeding place. Diminishing by a figure in unit's place establishes the sign of the first remainder (constant term), which must remain unchanged in the succeeding equations. The correct figure in a decimal place (not tenth's place) may usually be found by rejecting all but the last two terms of the equation, the assumption being that the value of the terms rejected will not affect the result. Caution must be observed in doing this, however. At a certain stage more than one figure can be found by dividing the last by the preceding coefficient (with sign changed).

Example. Calculate the root of $x^3 - 6x^2 + 3x + 5 = 0$ lying between 1 and 2. *Solution.* Diminish the roots by 1. New equation is $x^3 - 3x^2 - 6x + 3 = 0$. This equation has a root between 0.4 and 0.5. Diminish the roots by 0.4.

$$\begin{array}{l}
1 - 3.0 - 6.00 + 3.000 \;\underline{|\,0.4}\\
\underline{\quad + 0.4 - 1.04 - 2.816}\\
1 - 2.6 - 7.04(+ 0.184)\\
\underline{\quad + 0.4 - 0.88}\\
1 - 2.2(- 7.92)\\
\underline{\quad + 0.4}\\
1(- 1.8)
\end{array}$$

The transformed equation is $x^3 - 1.8x^2 - 7.92x + 0.184 = 0$. It has a root between 0 and 0.1. Neglecting the two first terms, $- 7.92x + 0.184 = 0$, $x = 0.02$. Diminish by 0.02. Transformed equation is $x^3 - 1.74x^2 - 7.9908x + 0.024888 = 0$. The root of this equation between 0 and 0.01 is $x = \dfrac{0.024888}{7.9908} = 0.003$. Hence root is 1.423 to three places.

The last division may be carried farther. $x = 0.024888 \div 7.9908 = 0.00311$. Value of rejected terms $(x^3 - 1.74x^2)$ for x between 0.003 and 0.004 lies between $- 0.000015$ and $- 0.000028$, therefore three figures may be found by division. The root is 1.42311 to 5 places.

Number of real roots. When two consecutive coefficients in an equation have like signs a PERMANENCE OF SIGN is said to occur, if unlike signs, a VARIATION OF SIGN occurs. DESCARTES' RULE OF SIGNS states that the number of positive roots cannot exceed the number of variations of sign, nor can the number of negative roots exceed the number of permanences of sign. Existence of imaginary roots may often be established by this rule.

Example. In $x^3 + 5x + 7 = 0$, no variation of sign occurs, therefore there is no positive root. Writing in x^2 with coefficient $- 0$, signs are $+ - + +$, only one permanence,

hence not more than one negative root. Equation has one real root which is negative and a pair of conjugate imaginary roots.

Sturm's theorem gives a method of determining the number of real roots between two numbers $x = a$, $x = b$. (**5**)

Solution of cubic equation, $x^3 + 3Hx + G = 0$.

Graphical solution. Plot $y = x^3$, and $y = -3Hx - G$. Abscissas of points of intersection are roots.

Formula. Put $J = G^2 + 4H^3$.

Case I. J positive. One root only is real, $x = \sqrt[3]{-\frac{1}{2}G + \sqrt{J}} + \sqrt[3]{-\frac{1}{2}G - \sqrt{J}}$.

Case II. $J = 0$. All roots are real and two equal $x_1 = 2\sqrt[3]{-\frac{1}{2}G} = x_2$.

Case III. J negative. Roots all real and distinct. Determine the angle t between 0° and 180° for which $\cos t = -G/2H\sqrt{-H}$. Roots are $x_1 = 2\sqrt{-H}\cos \frac{1}{3}t$, $x_2 = 2\sqrt{-H}\cos(\frac{1}{3}t + 120°)$, $x_3 = 2\sqrt{-H}\cos(\frac{1}{3}t + 240°)$.

To eliminate x^2 from $ax^3 + bx^2 + cx + d = 0$, put $z = ax + \frac{1}{3}b$, or $x = (3z - b)/3a$.

Graphical solution of any equation. Transpose such terms to second member as may be desirable, plot y = first member, and y = second member. Abscissas of points of intersection of graphs are roots.

14. Determinants

Formulas for solving linear systems can be written down in compact form by use of determinants, which are arrangements of numbers in the form of squares. (**5**) Examples and definitions are as follows:

Second order. $$\begin{vmatrix} a_1 & b_1 \\ a_2 & b_2 \end{vmatrix} = a_1b_2 - a_2b_1.$$

Third order. $$\begin{vmatrix} a_1 & b_1 & c_1 \\ a_2 & b_2 & c_2 \\ a_3 & b_3 & c_3 \end{vmatrix} = a_1 \begin{vmatrix} b_2 & c_2 \\ b_3 & c_3 \end{vmatrix} - a_2 \begin{vmatrix} b_1 & c_1 \\ b_3 & c_3 \end{vmatrix} + a_3 \begin{vmatrix} b_1 & c_1 \\ b_2 & c_2 \end{vmatrix}.$$

$$= a_1b_2c_3 - a_1b_3c_2 - a_2b_1c_3 + a_2b_3c_1 + a_3b_1c_2 - a_3b_2c_1.$$

Fourth order. $$\begin{vmatrix} a_1 & b_1 & c_1 & d_1 \\ a_2 & b_2 & c_2 & d_2 \\ a_3 & b_3 & c_3 & d_3 \\ a_4 & b_4 & c_4 & d_4 \end{vmatrix} = a_1 \begin{vmatrix} b_2 & c_2 & d_2 \\ b_3 & c_3 & d_3 \\ b_4 & c_4 & d_4 \end{vmatrix} - a_2 \begin{vmatrix} b_1 & c_1 & d_1 \\ b_3 & c_3 & d_3 \\ b_4 & c_4 & d_4 \end{vmatrix}$$

$$+ a_3 \begin{vmatrix} b_1 & c_1 & d_1 \\ b_2 & c_2 & d_2 \\ b_4 & c_4 & d_4 \end{vmatrix} - a_4 \begin{vmatrix} b_1 & c_1 & d_1 \\ b_2 & c_2 & d_2 \\ b_3 & c_3 & d_3 \end{vmatrix}.$$

The numbers are called ELEMENTS. If the row and column in which an element lies are erased, the determinant remaining is called the CORRESPONDING MINOR of that element. The value of a determinant is expressed as a sum of products of successive elements of a row (or column) by corresponding minors with alternating signs, as shown above for the elements of the first column.

Solution of linear systems

Two unknowns. $a_1x + b_1y = c_1$, $a_2x + b_2y = c_2$.

$$x = \begin{vmatrix} c_1 & b_1 \\ c_2 & b_2 \end{vmatrix} \div \begin{vmatrix} a_1 & b_1 \\ a_2 & b_2 \end{vmatrix}, \quad y = \begin{vmatrix} a_1 & c_1 \\ a_2 & c_2 \end{vmatrix} \div \begin{vmatrix} a_1 & b_1 \\ a_2 & b_2 \end{vmatrix}.$$

Three unknowns. $a_1x + b_1y + c_1z = d_1$, $a_2x + b_2y + c_2z = d_2$, $a_3x + b_3y + c_3z = d_3$.

$$D = \begin{vmatrix} a_1 & b_1 & c_1 \\ a_2 & b_2 & c_2 \\ a_3 & b_3 & c_3 \end{vmatrix} \neq 0. \quad x = \frac{\begin{vmatrix} d_1 & b_1 & c_1 \\ d_2 & b_2 & c_2 \\ d_3 & b_3 & c_3 \end{vmatrix}}{D}, \quad y = \frac{\begin{vmatrix} a_1 & d_1 & c_1 \\ a_2 & d_2 & c_2 \\ a_3 & d_3 & c_3 \end{vmatrix}}{D}, \quad z = \frac{\begin{vmatrix} a_1 & b_1 & d_1 \\ a_2 & b_2 & d_2 \\ a_3 & b_3 & d_3 \end{vmatrix}}{D}.$$

Similar formulas hold for any number of unknowns.

Properties of determinants. (1) Interchanging the corresponding elements of two columns (or rows) changes the sign of the determinant. (2) If corresponding elements of two rows (or columns) are identical, the determinant is zero. (3) Columns may be changed to rows and rows to columns. (4) If all the elements of a column are multiplied by a number m, the value of the determinant is multiplied by m. (5) The value of a determinant is unchanged, if the elements of a column are multiplied by m and added to corresponding elements of any other column.

15. Logarithms

Exponents. For any numbers m, n, the following formulas hold:—$a^m \times a^n = a^{m+n}$; $a^m/a^n = a^{m-n}$; $(a^m)^n = a^{mn}$; $a^0 = 1$; $1/a^n = a^{-n}$; $a^m b^m = (ab)^m$; $a^{\frac{1}{r}} = \sqrt[r]{a}$; $\sqrt[r]{a} \times \sqrt[r]{b} = \sqrt[r]{ab}$ (r a positive integer).

Radicals. A radical is an indicated root of an algebraic or arithmetic expression. Operations with radicals are performed by changing to exponents. $\sqrt[r]{A} = A^{1/r}$.

Example. $\sqrt{2} \times \sqrt[3]{3} = 2^{1/2} \times 3^{1/3} = 2^{3/6} \times 3^{2/6} = (2^3)^{1/6} \times (3^2)^{1/6} = 8^{1/6} \times 9^{1/6} = (72)^{1/6} = \sqrt[6]{72}$. *Ans.*

Division by radicals may be avoided by RATIONALIZING.

Example. To compute $\dfrac{\sqrt{3} + \sqrt{2}}{\sqrt{5} - \sqrt{3}}$, multiply numerator and denominator by $\sqrt{5} + \sqrt{3}$. This rationalizes the denominator, for $(\sqrt{5} - \sqrt{3})(\sqrt{5} + \sqrt{3}) = 5 - 3 = 2$, hence the value $\frac{1}{2}(\sqrt{3} + \sqrt{2})(\sqrt{5} + \sqrt{3}) = \frac{1}{2}(3 + \sqrt{6} + \sqrt{10} + \sqrt{15})$.

Logarithms are exponents of a given number called the BASE. (5) The system commonly used, COMMON LOGARITHMS, has the base 10. (See also Art. 4.) The common logarithm of any number is the exponent or power to which 10 must be raised to equal the number. If $10^x = N$, then $x = \log N$.

From $10^2 = 100$, and $0.1 = 1/10 = 10^{-1}$, it appears that $\log 100 = 2$, and $\log 0.1 = -1$. Also $10^0 = 1$, $\therefore \log 1 = 0$

From $10^x = m$, $10^y = n$, multiplying, $10^{x+y} = mn$. Hence the logarithm of a product equals the sum of the logarithms of the factors. For other rules, see Art. 4.

Any number may be written as the product of a number between 1 and 10 multiplied by an integral power of 10, positive or negative. The logarithm of a number between 1 and 10 is a number between 0 and 1. Hence the logarithm of any number may be written as the sum of a decimal (less than 1) called the MANTISSA, and an integer (positive or negative) called the CHARACTERISTIC. Tables of common logarithms give logarithms of numbers from 0 to 10 ($\log 0 = \infty$) to three, four, five, or more places of decimals (THREE-PLACE, FOUR-PLACE, FIVE-PLACE TABLES). (See Table 16 and "Use of Tables," Art. 75.)

Natural, or Napierian, logarithms. The base of this system is 2.71828 . . . (to five places), denoted by e. $10^{0.43429 \cdots} = 2.71828$. Common logarithm equals the natural logarithm times 0.43429, which number is called the MODULUS of the common system. Natural log = common log times 2.3026. The abbreviation NAP LOG is used for natural or Napierian logarithm.

16. Permutations and combinations

A PERMUTATION of any number of things is a group of some or all of them, arranged in a definite order. (**5**) The number of permutations of m different things taken r at a time is the product of successive decreasing integers from m down to $m - r + 1$. The number of permutations of m different things taken all together is the product of all integers from 1 to m. The product $1 \cdot 2 \cdot 3 \cdot \ldots \cdot m$ is called FACTORIAL m, and written $m!$ The formula for the number of permutations of m things r at a time is $m!/(m - r)!$

A COMBINATION of any number of things is a group of some or all of them, without reference to order in the group. The number of combinations of m different things r at a time equals the number of permutations divided by factorial r, namely $m!/(m - r)!r!$. Given two groups of m and n things respectively, the number of selections (combinations) of $r + s$ things, r from first group and s from second group equals $m!\ n!/(m - r)!\ (n - s)!\ r!\ s!$

17. Chance

The PROBABILITY that an event will happen is the ratio of the number of favorable cases to the whole number of cases that can occur. (**6**)

Example. From an urn containing 5 black and 4 white balls, 3 balls are drawn at random. What is the probability that 2 will be black and 1 white?

From 9 balls 3 may be drawn in $9 \times 8 \times 7/3! = 84$ ways. (This is the number of combinations of 9 things 3 at a time.) The number of favorable cases (formula above) is $5!\ 4!/3!\ 3!\ 2! = 40$. Hence the required probability is $40/84 = 10/21$, *i.e.*, 10 chances in 21.

If the probabilities of two events are a and b, respectively, the probability of simultaneous occurrence is ab, and of occurrence of one or the other is $a + b$.

Example. The probability of drawing a knave from a full pack of cards is 1/13. The probability of drawing a spade is 1/4. Hence the probability of drawing the knave of spades is $1/13 \cdot 1/4 = 1/52$. Probability of drawing a knave or an ace is $1/13 + 1/13 = 2/13$.

18. Progressions

An arithmetic progression is a sequence of terms each of which differs from the preceding by the same number d, called the COMMON DIFFERENCE. If n = number of terms, a = first term, l = last term, s = sum of n terms, then $l = a + (n - 1)d$, and $s = \frac{n}{2}(a + l)$. ARITHMETIC MEAN of two numbers is half their sum.

A geometric progression is a sequence of terms each of which is obtained from the preceding by multiplying it by a fixed number r, called the RATIO. If n = number terms, a = first term, l = last term, s = sum of n terms, then $l = ar^{n-1}$, $s = (rl - a)/(r - l)$. GEOMETRIC MEAN of two numbers m, n is $\sqrt{mn}$.

19. Binomial theorem

The binomial theorem is a formula for expanding a power of the sum of two terms.

$$(a + b)^n = a^n + na^{n-1}b + \frac{n(n-1)}{1 \cdot 2}a^{n-2}b^2 + \frac{n(n-1)(n-2)}{1 \cdot 2 \cdot 3}a^{n-3}b^3 + \ldots$$

If n is a positive integer, the right hand member contains $n + 1$ terms and the last term is b^n. The product of the coefficient in any term and the exponent

of a in that term divided by the exponent of b increased by 1 gives the coefficient of the next term. If n is not a positive integer, the sequence of terms of the second member does not terminate but leads to an INFINITE SERIES. The formula holds then only when $|b| < |a|$. (See under Series, Art. 62.)

Coefficients $1, n, \frac{n(n-1)}{1\cdot 2}, \frac{n(n-1)(n-2)}{1\cdot 2\cdot 3}, \frac{n(n-1)(n-2)(n-3)}{4!}$, etc.

are called BINOMIAL COEFFICIENTS. A convenient notation is $n = \binom{n}{1}$, $\frac{n(n-1)}{1\cdot 2} = \binom{n}{2}, \frac{n(n-1)(n-2)}{1\cdot 2\cdot 3} = \binom{n}{3}$, etc. When n = a positive integer, the rth coefficient from the beginning and the rth from the last are equal.

Binomial coefficients

r	$\binom{r}{2}$	$\binom{r}{3}$	$\binom{r}{4}$	$\binom{r}{5}$
0.1	−0.0450	0.0285	−0.0207	0.0161
0.2	−0.0800	0.0480	−0.0336	0.0255
0.3	−0.1050	0.0595	−0.0402	0.0297
0.4	−0.1200	0.0640	−0.0416	0.0300
0.5	−0.1250	0.0625	−0.0391	0.0273
0.6	−0.1200	0.0560	−0.0336	0.0228
0.7	−0.1050	0.0455	−0.0262	0.0173
0.8	−0.0800	0.0320	−0.0176	0.0113
0.9	−0.0450	0.0165	−0.0087	0.0054

20. Interpolation

Series of differences. From a given sequence a_1, a_2, a_3, a_4, etc., form the sequence of FIRST DIFFERENCES $a_2 - a_1, a_3 - a_2$, etc., obtained by subtracting each term from the preceding term. From this sequence a third series of SECOND DIFFERENCES may be formed, and so on.

Let b_1, b_2, b_3, etc., be the series of first differences;
c_1, c_2, c_3, etc., be the series of second differences;
d_1, d_2, d_3, etc., be the series of third differences.

The formula for $(n + 1)$th term of original sequence is $a_{n+1} = a_1 + nb_1 + \frac{n(n-1)}{1\cdot 2}c_1 + \frac{n(n-1)(n-2)}{1\cdot 2\cdot 3}d_1 + \ldots$ Formula for sum $(=s)$ of n terms is,

$$s = na_1 + \frac{n(n-1)}{1\cdot 2}b_1 + \frac{n(n-1)(n-2)}{1\cdot 2\cdot 3}c_1 + \ldots$$

Application of the formula is to cases when differences of a certain order all vanish. In an arithmetic progression, for example, second-order differences are zero.

Example. Find the sum of 11 terms of the series 1, 5, 12, 24, 43, 71, etc.

Solution. $a_1 = 1, b_1 = 4, c_1 = 3, d_1 = 2, n = 11.$
$s = 11 + 220 + 495 + 660 = 1386.$ *Ans.*

```
1   5   12   24   43   71
  4   7   12   19   28
    3   5    7    9
      2    2    2
        0    0
```

Sums of powers of integers 1, 2, 3, . . . n.

Sum of first powers $= \frac{1}{2}n(n + 1)$.
Sum of second powers $= \frac{1}{6}n(n + 1)(2n + 1)$.
Sum of third powers $= (\frac{1}{2}n(n + 1))^2$.

Interpolation by differences of higher order. A numerical table usually gives values $y_1, y_2, y_3, \ldots$ of a function y corresponding to values $x_1, x_2, x_3, \ldots$ of x. Successive values of x differ by a constant difference d (form an arithmetic progression.) From the values of y, form a series of differences of the first order, second order, etc., and let D_1, D_2, etc., be the first terms, respectively, of these series. To interpolate a value of y, say y', corresponding to the value $x' = x_1 + rd(d = x_2 - x_1,\ r < 1)$ of x between x_1 and x_2, use INTERPOLATION FORMULA,

$$y' = y_1 + rD_1 + \frac{r(r-1)}{1 \cdot 2} D_2 + \frac{r(r-1)(r-2)}{1 \cdot 2 \cdot 3} D_3 + \ldots$$

Differences above a certain order are assumed very small.

If differences above the first order are negligible, the formula $(y' = y' + rD_1)$ becomes the usual proportion $(y' - y_1) : (x' - x_1) = (y_2 - y_1) : (x_2 - x_1)$, for INTERPOLATION BY FIRST DIFFERENCES.

In using the above formula attention should be paid to the remarks under "addition" in approximate computation (Art. 1).

21. Complex numbers

If a and b are real numbers, $a + b\sqrt{-1}$ is a COMPLEX NUMBER. Write $i = \sqrt{-1}$, $i^2 = -1$. Number i is called IMAGINARY UNIT. When $a = 0$, the complex number is a pure imaginary, or simply imaginary, number. Complex numbers differing only in the sign of the imaginary part are said to be CONJUGATE. Point with coordinates (a, b) represents $a + bi$ graphically. (Fig. 21.) Real numbers are represented by points on X-axis (number scale), imaginary numbers by points on Y-axis. Formal laws of operation in algebra apply to complex numbers, remembering always that $i^2 = -1$. This representation of complex numbers is a counterpart of the number scale for real numbers, Art. 6.

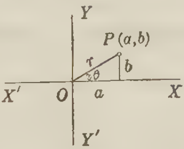

FIG. 21.

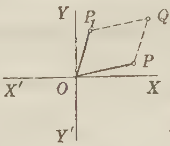

FIG. 22.

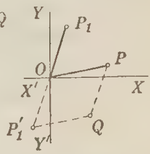

FIG. 23.

Addition. The sum of $a + bi$ and $a_1 + b_1 i$ is $(a + a_1) + (b + b_1)i$.

To construct graphically point Q corresponding to the sum of numbers represented by P and P_1, draw parallelogram $OPQP_1$. (Fig. 22.) Regarding OP and OP_1 as vectors, the operation of addition is VECTOR ADDITION.

Subtraction. Difference of $a + bi$ and $a_1 + b_1 i$ is $(a - a_1) + (b - b_1)i$.

To construct corresponding point Q, plot $P_1'(-a_1, -b_1)$, and draw parallelogram $OPQP_1'$. (Fig. 23.)

The absolute value and amplitude of $a + bi$ are respectively the polar coordinates r and θ (Art. 48) of $P(a, b)$. (Fig. 21.)

$$r = +\sqrt{a^2 + b^2} = |a + bi|. \quad a = r\cos\theta, \quad b = r\sin\theta.$$

Hence $a + bi = r(\cos\theta + i\sin\theta)$.

Absolute value r is also called MODULUS, and amplitude θ ANGLE or ARGUMENT. The amplitude given by $a = r\cos\theta$, $b = r\sin\theta$ is a unique angle less than 360°.

Multiplication of $a + bi$ and $a_1 + b_1i$. Write in polar form $a + bi = r(\cos\theta + i\sin\theta)$, $a_1 + b_1i = r_1(\cos\theta_1 + i\sin\theta_1)$. Then $(a + bi)(a_1 + b_1i) = rr_1[\cos(\theta + \theta_1) + i\sin(\theta + \theta_1)]$.

The absolute value of the product of two complex numbers is the product of the absolute values, and the amplitude is the sum of the amplitudes. Multiplication by i has the effect of rotating a point through 90°, by $i^2 = -1$ through 180°, by $i^3 = -i$, through 270°.

Division of two complex numbers $a + bi$ and $c + di$ is worked as below.

$$\frac{a + bi}{c + di} = \frac{a + bi}{c + di} \times \frac{c - di}{c - di} = \frac{ac + bd + (bc - ad)i}{c^2 + d^2}.$$

Absolute value of the quotient of two complex numbers is the quotient of the absolute values of numerator and denominator, and the amplitude of the quotient is the difference of the amplitudes of numerator and denominator.

Powers and roots. For a positive integer n, $(a + bi)^n = r^n(\cos\theta + i\sin\theta)^n = r^n(\cos n\theta + i\sin n\theta)$.

When $r = 1$, this is known as DeMoivre's theorem.

$$\sqrt[n]{a + bi} = \sqrt[n]{r}\,(\cos\theta + i\sin\theta)^{\frac{1}{n}} = \sqrt[n]{r}\,(\cos\theta/n + i\sin\theta/n).$$

In this formula, θ has n values differing by 360°, namely, θ_1 (amplitude of $a + bi < 360°$), $\theta_1 + 360°$, $\theta_1 + 720°$, . . . , $\theta_1 + (n - 1)$ 360°. The nth root of a real number has n distinct values, one real, the others complex.

Cube roots of unity are found by setting $n = 3$, $r = 1$, $\theta = 0$, 360°, 720°. They are 1, $\cos 120° + i\sin 120°$, $\cos 240° + i\sin 240°$, that is, 1, $-1/2 + \sqrt{-3/2}$, $-1/2 - \sqrt{-3/2}$. Points representing these roots are the vertices of an equilateral triangle inscribed in a circle drawn with unit radius about the origin, one vertex being (1, 0). Similarly, the vertices of a regular polygor of n sides inscribed in this circle, one vertex (1, 0), will represent the nth roots of unity.

Exponentials, trigonometric functions, and complex numbers. The relations are

$$e^{ix} = \cos x + i\sin x,$$
$$\sin x = (e^{ix} - e^{-ix})/2i;$$
$$\cos x = (e^{ix} + e^{-ix})/2.$$

From these relations, $e^{2\pi i} = 1$; $e^{\pi i} = \cos\pi + i\sin\pi = -1$; $e^{\pi i/2} = i$; $e^{\pi i/4} = +\sqrt{i} = \cos\pi/4 + i\sin\pi/4$.

Logarithm of a complex number $a + bi = re^{i\theta}$ is a complex number, $\log r + i\theta$. Since θ may be replaced by $\theta + 2n\pi$ (n any integer), $\log(a + bi) = \log r + i(\theta + 2\pi n)$. Points representing $\log(a + bi)$ lie on a line parallel to Y-axis, to the right a distance equal to $\log r$.

22. Precision of measurements. Least squares. Probable error.

If a number of measurements are made to determine directly the unknown magnitude of a certain object, all measurements being made with equal skill and care, the most probable value of the unknown is the arithmetical mean of all the measurements. That is, with n measurements $x_1, x_2, x_3 \ldots x_n$, the most probable value x_0 is $x_0 = (x_1 + x_2 + x_3 + \cdots + x_n)/n$. (6)

The basis for this assumption is that, on the average, errors in excess (positive errors), and errors in defect (negative errors) are evenly balanced, so that the sum of the errors is zero. If the unknown magnitude is x, it can be readily shown by Calculus (Art. 57) that

the most probable value is that for which the SUM OF THE SQUARES OF THE ERRORS, viz.: $(x_1 - x)^2 + (x_2 - x)^2 + \ldots + (x_n - x)^2$ is a minimum. Hence the name LEAST SQUARES.

Weighted measurements. If the method of making measurements shows that weights w_1, w_2, etc., should be assigned to measurements x_1, x_2, etc., then the most probable value of the unknown is the WEIGHTED MEAN, $x_0 = (w_1x_1 + w_2x_2 + \ldots + w_nx_n)/(w_1 + w_2 + \ldots + w_n)$.

Residuals are differences $x_1 - x_0$, $x_2 - x_0$, etc., between the observed values and the most probable value, and are denoted by v_1, v_2, etc. Evidently $v_1 + v_2 + \ldots + v_n = 0$.

Probable error of an observation is a number such that the actual error of that observation may with equal chances be greater or less than the probable error. For example, if a measurement is 30.726 with a probable error of $\pm$ 0.014, the meaning is that the correct value is just as likely to lie between 30.712 and 30.740 as outside these limits. The probable error gives a measure of the precision of a measurement. Weights to be attached to different determinations of the same quantity are inversely proportional to the squares of the probable errors. Formulas for computing probable error follow. Numerical values of residuals are $|v_1|$, $|v_2|$, etc., number of observations is n.

Probable error (r) **of single observation,**

$$r = \frac{0.6745}{\sqrt{n-1}}\sqrt{v_1^2 + v_2^2 + \ldots + v_n^2}. \qquad \text{(STANDARD FORMULA.)}$$

$$r = \frac{0.8453}{\sqrt{n(n-1)}}(|v_1| + |v_2| + \ldots |v_n|).$$

(PETER'S FORMULA, approximate.)

Probable error (r_0) **of arithmetical mean,**

$$r_0 = r/\sqrt{n}; \quad r_0 = \frac{0.6745}{\sqrt{n(n-1)}}\sqrt{v_1^2 + v_2^2 + \ldots + v_n^2}.$$

(STANDARD FORMULA.)

$$r_0 = \frac{0.8453}{n\sqrt{n-1}}(|v_1| + |v_2| + \ldots + |v_n|).$$

(PETER'S FORMULA, approximate.)

For tables of values of coefficient of parentheses, see (6).

Example. The following are ten measurements M of the length of a base line. Below are given the values of residuals, v, and the squares of residuals.

M: 455.35, 455.35, 455.20, 455.05, 455.75, 455.40, 455.10, 455.30, 455.50, 455.30.

M_0 = arithmetic mean = 455.330.

v: .02, .02, $-$.13, $-$.28, .42, .07, $-$.23, $-$.03, .17, $-$.03.

v^2: .0004, .0004, .0169, .0784, .1764, .0049, .0529, .0009 .0289, .0009.

Hence $v_1^2 + v_2^2 + \ldots + v_n^2 = .3610$. And $|v_1| + |v_2| + \ldots + |v_n| = 1.40$.

$\therefore$ by the standard formulas, $r = \frac{0.6745}{\sqrt{9}}\sqrt{.3610} = .13$, $r_0 = r/\sqrt{10} = .042$.

By the approximate formulas, $r = \frac{0.8453}{\sqrt{90}}(1.40) = .12$. $r_0 = .039$.

For the most probable length of the base line, the result is 455.330 with probable error $\pm$ .042 (using result given by standard formula), usually written 455.330 $\pm$ .042. Note also that five of the residuals are numerically less than the probable error of a single observation. In fact, in any considerable number of observations it should be the case that half of the residuals are less than the probable error.

Probable error of a function of a single measured quantity equals the product of the derivative of the function (Art. 56) by the probable error of the measured quantity.

To test a given set of measurements of an unknown quantity, make use of the normal distribution of residuals for the purpose of obtaining a comparison of the data of the experiment with results established by theory and confirmed by practice. By the table below, the normal number of residuals ($= y$) numerically less than an assumed value ($= a$) can be written down. In the table the number of measurements is n, and the probable error of a single observation is r

Table of values of ratio y/n

a/r	.0	.1	.2	.3	.4	.5	.6	.7	.8	.9
0	.000	.054	.107	.160	.213	.264	.314	.363	.4105	.456
1	.500	.542	.582	.619	.655	.688	.7195	.7485	.775	.800
2	.823	.843	.862	.879	.8945	.908	.9205	.931	.941	.9495
3	.957	.9635	.969	.974	.978	.982	.985	.987	.990	.9915
4	.993	.994	.995	.996	.997	.998	.998	.9985	.9988	.999
5	.999									
∞	1.000									

Example. In an experiment 40 measurements were made and the probable error of a single observation was $r = 0.136$. For $a = 0.05$, $a/r = 0.37$. The above table gives $y/n = 0.196$. Hence $y = 7.84$, that is, there should be normally 8 residuals not exceeding 0.05 in numerical value. Values of y are tabulated corresponding to assumed values of a, and under Y is written down the normal distribution of residuals for the experiment, namely, 8 residuals not exceeding 0.05, 7 residuals numerically between 0.05 and 0.10, inclusive, etc. Actual numbers of residuals are given in the last column, and comparison shows a satisfactory result.

a	a/r	y	Y	
0.00	0.00	0.00		
0.05	0.37	7.84	8	9
0.10	0.74	15.2	7	6
0.20	1.5	27.5	12	12
0.30	2.2	34.5	7	8
0.40	2.9	38	4	3
∞	∞	40	2	2

To test whether any measurement should be rejected. Calculate y/n by the formula $y/n = (2n - 1)/2n$, and from the above table find a/r, and then a. This value of a gives a maximum numerical value for all residuals, and any measurement in which the residual exceeds this value should be rejected.

Example. In the experiment above, $n = 40$, and $y/n = (80 - 1)/80 = 0.987$. Hence $a/r = 3.7$, and $a = 3.7 \times 0.136 = 0.50$. No residual should exceed 0.50 in numerical values. Maximum residual in the experiment was 0.45.

Constant errors due to some fixed cause such as conditions under which the experiment was made, defects in instruments, personal peculiarity of observer, etc., are supposed to have been detected and eliminated before the methods explained above are applied.

Solution of a system of linear equations by least squares. The problem of determining the empirical law satisfied by given data (Art. 71) involves the solution of a system of linear equations in which the number of equations exceeds the number of unknowns. For such a system the question is the most probable values of the unknowns. The method of solution of a system with three unknowns x, y, z illustrates the general method. **(6)**

Example. The data of the experiment establish a system of n OBSERVATION EQUATIONS with unknowns x, y, z. Form a system of NORMAL EQUATIONS equal in number to the number of unknowns as follows: (1) Multiply each observation equation by the coefficient of x in that equation, and add the resulting equations. This gives the first normal equation in which $a_1^2 + a_2^2 + \ldots + a_n^2 = [aa]$; $a_1b_1 + a_2b_2 + \ldots + a_n b_n = [ab]$, etc., adopting a convenient notation. (2) Multiply each observation equation by the coefficient of y in that equation, and add the resulting equations. This gives the second normal equation. (3) Multiply each observation equation by the coefficient of z in that equation, and add the resulting equations. This gives the third and, in this example, last normal equation. (4) Solve the normal equations for x, y, z. For these values, x', y', z', the sum of the squares of the left-hand members of the observation equations will be less than for any other values of x, y, z.

$$\begin{gathered} a_1x + b_1y + c_1z + d_1 = 0 \\ a_2x + b_2y + c_2z + d_2 = 0 \\ \cdot \quad \cdot \quad \cdot \quad \cdot \\ \cdot \quad \cdot \quad \cdot \quad \cdot \\ \cdot \quad \cdot \quad \cdot \quad \cdot \\ a_nx + b_ny + c_nz + d_n = 0. \end{gathered}$$

Normal equations

$$\begin{aligned} [aa]x + [ab]y + [ac]z + [ad] &= 0 \\ [ba]x + [bb]y + [bc]z + [bd] &= 0 \\ [ca]x + [cb]y + [cc]z + [cd] &= 0 \end{aligned}$$

The problem is to be regarded as one in which n observations are made upon the linear function $ax + by + cz + d$ of x, y, z, each observation establishing a set of values of a, b, c, d. The probable error r of a single observation is given by

$$r = \frac{0.6745}{\sqrt{n - q}}\sqrt{v_1^2 + v_2^2 + \ldots + v_n^2}, \text{ (standard formula)},$$

or

$$r = \frac{0.8453}{\sqrt{n(n - q)}}(|v_1| + |v_2| + \ldots + |v_n|), \text{ (approximate formula)},$$

where

$$q = \text{the number of unknowns}, \; v_1 = a_1x' + b_1y' + c_1z' + d_1,$$
$$v_2 = a_2'x' + b_2y' + c_2z' + d_2, \text{ etc.}$$

23. Interest and annuities

Compound interest. Let P = principal, i = interest on one dollar per year, n = number of years, A = amount after n years. Then $A = P(1 + i)^n$, when interest is compounded annually.

$A = P(1 + i/t)^{nt}$, when interest is compounded t times per year. From the first formula, $P = A/(1 + i)^n$, which gives the principal when the other quantities are known; $n = (\log A - \log P)/\log (1 + i)$, giving time.

Table 29, p. 1488, gives values of A when $P = 1$, $t = 1$, that is, gives values of A computed by the formula $A = (1 + i)^n$. This table can be used also when interest is compounded more often than once a year by taking i/t as percentage rate, and nt as number of years. For example, if interest is compounded semi-annually, halve the rate and double the time. To find amount, multiply the number in the table by the principal. Table 30, p. 1489, gives the principal which will amount to (present value of) one dollar in a given time at a given rate when interest is compounded annually, that is, is computed from $P = 1/(1 + i)^n$. For interest periods less than one year, proceed as above. To find the present value of any sum (discount any sum), multiply tabular number by this sum. (7)

An annuity is a series of equal payments made at equal periods of time, the first payment being made at the end of the first period. Let R = payment, i = interest on one dollar per year, n = number of years during which payments are continued, A = amount of annuity after n years, P = present value, then $A = R[(1 + i)^n - 1]/i$, when payments are made annually and interest is compounded annually.

Table 31, p. 1490, gives the amount of an annuity of one dollar for various rates and periods. For the amount of an annuity of any sum, multiply the tabular number by the sum. Formula for present value is $P = R(1 - (1 + i)^{-n})/i$. Table 32, p. 1491, gives the present value of an annuity of one dollar extending over a given period with money at a

given rate. For the present value of an annuity of any sum, multiply the tabular number by the sum. Table 33, p. 1492, gives the annuity which will amount to one dollar in a given time at a given rate. (Tabular numbers are reciprocals of those in Table 31.) To find the annual payment which will amount to a given sum in a given time at a given rate (SINKING FUND), multiply the tabular number by the sum.

Example. To provide a sinking fund of \$100,000 in 20 years if money accumulates at 4 per cent, the annual sum to be set aside equals 100,000 $\times$ 0.033582 (tabular number in Table 33 opposite 20 years under 4 per cent.), that is \$3358.20. *Ans.*

Annuity which a given sum P will purchase, when the annuity is to extend over a given period and money is worth a given rate, is found as follows: add the given rate in cents to the tabular number in Table 33, which corresponds to period and rate, and multiply the sum by P.

Example. For 20 years at rate 4 per cent., the tabular number in Table 33 is 0.033582. Adding .04 gives 0.073582. Hence \$100,000 will purchase an annuity of \$7358.20 terminating after 20 years, when money is worth 4 per cent.

24. Mine valuation (8)

The annual profit earned by a mine may be regarded as an annuity which must provide a dividend return on capital plus an annual sum to be set aside for a sinking fund that will amortize the capital. The value of the mine is the present value of the annual profit so regarded. If P = the annual profit assured for a period of years, value of mine is found as follows: Find the tabular number for period and rate earned by payments into sinking fund from Table 33, p. 1492. Add the dividend on one dollar to this number and divide the annual profit by the sum. (Table 5 is useful to replace division by multiplication.)

Example. Annual profit is estimated at \$200,000 for ten years. Payments into sinking fund earn 4 per cent. and dividend on capital invested is 7 per cent. Tabular number (Table 33) for 10 years and 4 per cent. is 0.083291. Adding dividend rate .07, gives 0.153291. Reciprocal of 0.1533 (Table 5) = 6.523. Present value of mine = 6.523 $\times$ 200,000 = \$1,304,600. *Ans.*

To determine the number of years that a given rate of income on capital must continue in order to amortize capital, pay a given rate of interest on capital, with annual payments into a sinking fund accumulating at a given rate per cent., proceed as follows: In Table 33, in the column under "Rate of accumulating sinking fund," find the number equal to the difference between the rate of income earned and the dividend rate. Then the time required is the corresponding value of time in the first column (interpolation may be used if justified by the problem.)

Example. Rate of income earned is 10 per cent., dividends paid 7 per cent., sinking fund accumulates at 4 per cent. Then from Table 33, under 4 per cent., number .03(= .10 − .07) occurs for a time between 21 and 22 years. (Interpolation gives 21.6 years.)

ELEMENTARY GEOMETRY

25. Plane figures

Triangles. The sum of the angles equals 180°. $\angle XAB$ is an exterior angle of ΔABC (Fig. 24). The exterior angle equals the sum of the opposite interior angles. ($\angle XAB = \angle B + \angle C$.) The MEDIAN of a triangle is the line joining a vertex to the midpoint of the opposite side. The medians

(Fig. 24) of a triangle meet in a point G, which is the center of gravity of the triangle, and G trisects each median. ($AG = \frac{2}{3}AD$.) BISECTORS OF ANGLES of a triangle meet in a point M equidistant from all sides. (Fig. 25.) M is the center of the circle tangent to the sides of the triangle, called INSCRIBED CIRCLE. M is INCENTER of triangle. The bisector of an angle of a triangle divides the opposite side into segments proportional to the other two sides. $AE : EC = AB : BC$. (Fig. 25.) ALTITUDES of a triangle meet in a point, the ORTHOCENTER. The perpendicular bisectors of the sides of a triangle meet in a point O (Fig. 26) equidistant from all vertices. O is the center of a circle passing through all vertices, called CIRCUMSCRIBED CIRCLE. O is CIRCUMCENTER of triangle. The longest side of a triangle is opposite the largest angle and *vice versa*. The line joining the mid-points of two sides of a triangle is parallel to the third side and half its length.

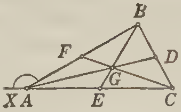

FIG. 24.

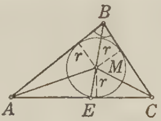

FIG. 25.

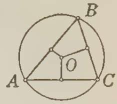

FIG. 26.

Orthogonal projection. In Figs. 27 and 28, AE is the orthogonal projection of AB on AC, BE being perpendicular to AC. The square of the side opposite an acute angle equals the sum of the squares of the other two sides diminished by twice the product of one of these sides by the orthogonal projection of the other side upon it. In Fig. 27, $a^2 = b^2 + c^2 - 2b \cdot AE$. The square of the side opposite an obtuse angle equals the sum of the squares of the other two sides increased by twice the product of one of these sides by the orthogonal projection of the other side upon it. In Fig. 28, $a^2 = b^2 + c^2 + 2b \cdot AE$.

Right triangle (Fig. 29). $\angle A + \angle B = 90°$. $c^2 = a^2 + b^2$. The ALTITUDE CE ($= h$) drawn from vertex of right angle C upon HYPOTENUSE (c), divides the hypotenuse into segments AE ($= m$) and BE ($= n$). Then $h^2 = mn$, $b^2 = cm$, $a^2 = cn$. The median drawn from C equals $\frac{1}{2}c$.

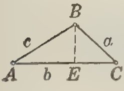

FIG. 27.

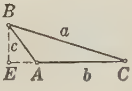

FIG. 28.

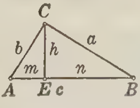

FIG. 29.

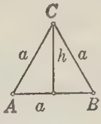

FIG. 30.

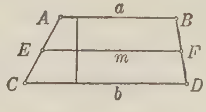

FIG. 31.

Equilateral triangle. (Fig. 30.) Side $= a$. Each angle $= 60°$. Altitude, $h = \frac{1}{2}a\sqrt{3}$. Radius of the circumscribed circle, $R = \frac{1}{3}a\sqrt{3}$. Radius of the inscribed circle, $r = \frac{1}{6}a\sqrt{3}$.

A trapezoid is a figure bounded by four lines, two of which are parallel (Fig. 31). ALTITUDE is the perpendicular distance between the parallel sides. MID-LINE (EF) joins the midpoints of the non-parallel sides and equals half the sum of the parallel sides. ($m = (a + b)/2$).

Sum of interior angles of a polygon equals 180° multiplied by the number of sides less two.

Circles. A straight line perpendicular to a radius of a circle at its extremity is tangent to the circle. Parallel lines intercept equal arcs on a circle.

When two circles intersect, the line of centers bisects the common chord at right angles. If two circles are tangent to each other, the line of centers passes through the point of contact.

Areas of two circles have the same ratio as the squares of their diameters or radii.

Angle measurement. The angle inscribed in a semi-circle is a right angle. The angle formed by two chords intersecting on a circle (INSCRIBED ANGLE) is measured by half the arc intercepted between its sides.

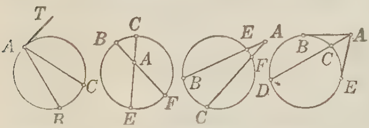

Fig. 32. Fig. 33. Fig. 34. Fig. 35.

In Fig. 32, $\angle BAC$ is measured by half arc BC.

The angle formed by a tangent and a chord drawn from the point of contact is measured by half the intercepted arc.

In Fig. 32, $\angle BAT$ is measured by $\frac{1}{2}$ arc BCA.

The angle formed by two chords intersecting within a circle is measured by half the sum of the intercepted arcs.

In Fig. 33, $\angle BAC$ (or EAF) is measured by $\frac{1}{2}$ (arc BC + arc EF).

The angle formed by two secants, or two tangents, or a tangent and a secant, intersecting without a circle, is measured by half the difference of the intercepted arcs.

In Fig. 34, $\angle BAC$ is measured by $\frac{1}{2}$ (arc BC − arc EF). In Fig. 35, $\angle BAE$ is measured by $\frac{1}{2}$ (arc BDE − arc BCE). In Fig. 35, $\angle BAC$ is measured by $\frac{1}{2}$ (arc BD − arc BC).

Chords, secants, and tangents. In Fig. 33, the product of segments AC and AE equals the product of segments AB and AF. In Fig. 34, the product of the whole secant AB and the external segment AE equals the product of the whole secant AC and its external segment AF. In Fig. 35, the product of the whole secant AD and the external segment AC equals the square of tangent AB (or AE).

Similar figures. Similar polygons have their angles respectively equal and the homologous sides proportional. Two triangles are similar if their angles are respectively equal, or if their sides are respectively proportional, or if they have an angle of one equal to an angle of the other and the including sides proportional. Areas of two similar polygons are to each other as the squares of homologous sides.

Regular figures. A regular polygon is one with equal sides and equal angles. A circle may be drawn to pass through all vertices of a regular polygon (CIRCUMSCRIBED CIRCLE), or to be tangent to every side (INSCRIBED CIRCLE). Two regular polygons of the same number of sides are similar.

26. Geometrical constructions

To bisect a given straight line AB (Fig. 36). With A and B as centers and with equal radii sufficiently great, describe arcs intersecting at C and D. Draw CD, cutting AB at E. Then E is the mid-point of AB.

To bisect a given angle CAB (Fig. 37). With A as center, and with any convenient radius AD describe an arc cutting AC in D and AB in E.

With D and E as centers and with equal radii sufficiently great, describe arcs intersecting in F. Draw AF. Then AF bisects $\angle A$.

To erect a perpendicular at a given point C, **in a line** AB. (1) Lay off $CD = CE$, (Fig. 38), and with D and E as centers and with equal radii sufficiently great, describe arcs intersecting at F. Draw FC, the perpendicular required. Or (2), (Fig. 39), take any convenient point D not on AB and with radius DC describe a circle cutting AB in E. Draw diameter EDF. Then FC is the required perpendicular.

To drop a perpendicular from a point C **to a line** AB. (1) With C as center and a radius sufficiently great (Fig. 40), describe an arc cutting AB in D and E. With D and E as centers, describe arcs intersecting at F. Draw CF, cutting AB in G. Then CF is the required perpendicular. (2) When C is nearly above one end of the line (Fig. 41), with C as center and radius 5 convenient units describe an arc cutting AB at D. Lay off DF equal to 4 units and draw CF, the required perpendicular.

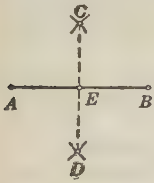

Fig. 36.

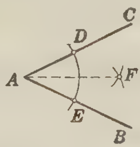

Fig. 37.

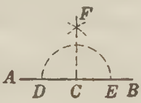

Fig. 38.

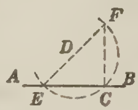

Fig. 39.

Fig. 40.

To draw a line through a given point C **parallel to given line** AB (Fig. 42). Draw CD perpendicular to AB, and erect a perpendicular CE to CD at C. Then CE is parallel to AB.

To draw a line parallel to a given line AB **at a given distance from it** (Fig. 43). With the given distance as radius and with any centers m and n on AB describe arcs xy and zw, respectively. Draw CD touching these arcs. Then CD is the required line.

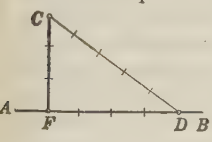

Fig. 41.

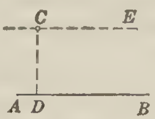

Fig. 42.

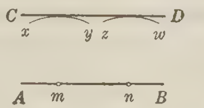

Fig. 43.

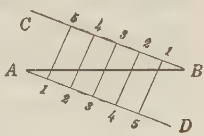

Fig. 44.

To divide a line AB **into a given number of equal parts** (Fig. 44). Draw AD making any angle with AB and draw BC parallel to AD. With dividers lay off equal lengths on AD and BC a number of times one less than the number of equal parts into which AB is to be divided. Number the points of division consecutively from A and from B and join as in the figure. The connecting lines will divide AB as required.

To construct an angle equal to a given angle ABC **when one side** FG **and the vertex** F **are given** (Fig. 45). With center B and a convenient radius BD describe arc DE. With the same radius and center F, draw arc KL. With radius equal to chord DE and with center K draw an arc cutting the arc KL at H. Draw FH. Then HFG is the required angle.

To lay out a circular arc of large radius. (Fig. 46.) Let AB be the chord of the desired arc and MC the height, MC being the perpendicular bisector of AB. Draw CB, and at B erect BF perpendicular to CB and BG perpendicular to AB. Divide CF, MB, BG into the same number of equal parts. Connect corresponding points of division on CF and MB, and draw lines from C to points of division on BG, as in the figure. In this manner as many points on the required arc can be determined as desired.

Let $CM = h$, $AB = 2b$. Then radius of arc $= (b^2 + h^2)/2h$.

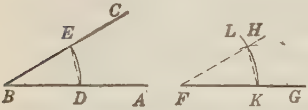

FIG. 45.

FIG. 46.

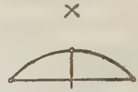

FIG. 47.

To bisect a given arc of a circle, draw the perpendicular bisector of the chord of the arc (Fig. 47). The point in which this bisector meets the arc is the required mid-point.

To circumscribe a circle about a given triangle (Fig. 48). Construct perpendicular bisectors of two sides. Their point of intersection is the center (circumcenter) of the required circle.

To inscribe a circle in a given triangle (Fig. 49). Draw bisectors of two angles intersecting in O (incenter). From O, draw OD perpendicular to BC. Then a circle with center O and radius OD is the required circle.

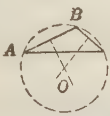

FIG. 48.

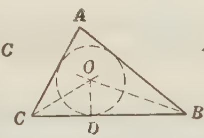

FIG. 49.

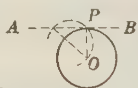

FIG. 50.

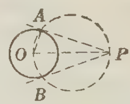

FIG. 51.

To draw a tangent to a given circle through a given point (P). (1) *When P is on circle,* (Fig. 50), draw radius OP, and construct AB perpendicular to OP at P. Then AB is the required tangent. (2) *When P is without the circle* draw a line joining P and O, the center of circle. (Fig. 51.) With OP as diameter describe a circle intersecting the given circle at A and B. Draw PA and PB. Each of these lines is tangent to the given circle.

To draw a common tangent to two given circles, with centers O and O' and unequal radii r and r', $r > r'$. When the given circles do not intersect (Fig. 52), to draw a COMMON INTERNAL TANGENT, construct a circle having same center O as larger circle and a radius equal to the sum of the radii of the given circles $(r+r')$. Construct a tangent $O'P'$ from center O' of the small circle to this circle. Construct $O'N$ perpendicular to this tangent. Draw OP'. The line MN joining the extremities of the radii OM and $O'N$ will be a common tangent. The figure shows two such common internal tangents. To draw a COMMON EXTERNAL TANGENT to two circles (Fig. 53), construct a circle having

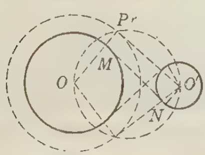

FIG. 52.

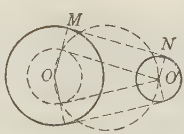

FIG. 53.

a common center with the larger circle and radius equal to the difference of radii $(r - r')$. Construct a tangent to this circle from the center of the smaller circle. The line joining the extremities M, N, of the radii of the given circles perpendicular to this tangent is the required common tangent. There are two such tangents.

In Fig. 52, $MN = \sqrt{c^2 - (r + r')^2}$, when $OO' = c$. In Fig. 53, $MN = \sqrt{c^2 - (r - r')^2}$.

To divide a given line AB into segments proportional to any number of given lines (Fig. 54). Draw AC, making any convenient angle with AB. Lay off AD, DE, and EF equal to the given lines m, n, p. Draw FB, and construct EH and DG parallel to FB. Then AG, GH, HB are the required segments.

To construct the mean proportional between two given lines (Fig. 55). Draw a line AC on which AB and BC equal the given lines, a, b. Construct semi-circle on AC as diameter. Erect a perpendicular to AC at B, intersecting the semi-circle at D. Then BD is the mean proportional between AB and BC.

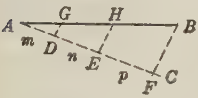

FIG. 54.

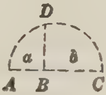

FIG. 55.

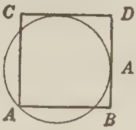

FIG. 56.

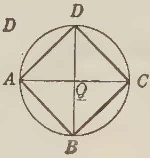

FIG. 57.

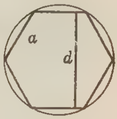

FIG. 58.

To construct a square with a given side AB (Fig. 56), erect a perpendicular at A, lay off $AC = AB$, and from C and B as centers with radius equal to AB describes arcs intersecting at the fourth vertex D.

To construct a square with a given diagonal AC (Fig. 57), draw a circle on AC as diameter, and erect the diameter BD perpendicular to AC. Then $ABCD$ is the required square.

To inscribe a square in a given circle, draw perpendicular diameters AC and BD (Fig. 57). Their extremities are the vertices of the inscribed square.

To inscribe a hexagon in a circle, step around the circle with dividers set to the radius (Fig. 58).

To construct a hexagon with a side of given length, draw a circle with radius equal to given side, and inscribe a regular hexagon in this circle.

If the side of a regular hexagon $= a$, and the distance between parallel sides $= d$, then $d = a\sqrt{3} = 1.732\,a$.

To draw a regular polygon of any desired number of sides, when one side AB is given, draw a semi-circle with radius AB (Fig. 59), and divide this semi-circle into as many equal parts BC, CD, DE, etc., as the required polygon has sides. Draw a line from A through each point of division except the last, and complete the construction as in the figure.

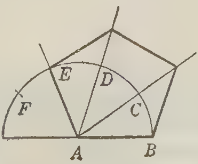

FIG. 59.

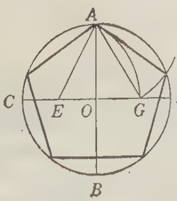

FIG. 60.

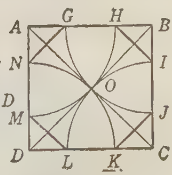

FIG. 61.

To inscribe a regular pentagon in a given circle, draw perpendicular diameters AB and CD (Fig. 60). Bisect radius OC at E. With E as center, strike an arc through A cutting OD at G. Then AG equals a side of the pentagon required.

To inscribe a regular octagon in a circle, draw perpendicular diameters, and bisect each of the four equal arcs determined by the extremities of these diameters.

To convert a square into an octagon, draw diagonals AC and BD, intersecting at O (Fig. 61). With vertices A, B, C, D as centers and radius AO draw arcs cutting the sides of the square in eight points. These points are vertices of a regular octagon.

27. Loci

All points equidistant from a given point lie on a circle whose center is the given point. All points equidistant from two given points lie on perpendicular bisector of the line joining the given points. All points equidistant from the sides of a given angle lie on the bisector of the angle. If a point moves. so that the ratio of its distances from two fixed points remains constant, it will lie upon a circle. In Fig. 62, PA/PB remains constant while P describes the circle. Diameter DE is determined by drawing bisectors of angles APB and BPE. (See Art. 25.) If a side AB and the opposite angle of a triangle (Fig. 63) are given, vertex E of angle will lie on a circle of which the given side is a chord. This circle is constructed as follows: Construct $\angle ABC$ equal to the given angle. Erect BM perpendicular to CB and draw the perpendicular bisector DP of AB. The point of intersection of BM and DP is the center of the required circle.

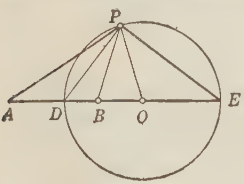

FIG. 62.

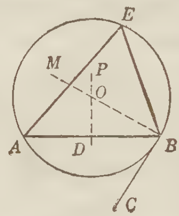

FIG. 63.

28. Solid geometry

Common solids. Figures 64–77 illustrate solids of common occurrence.

FIG. 64.

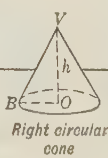

FIG. 74.

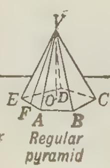

FIG. 75.

FIG. 76.

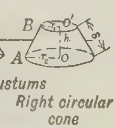

FIG. 77.

Dihedral angle (Fig. 78) is a figure formed by two planes meeting in a line, called an EDGE, and not extending beyond the line. The planes are called FACES. The angle formed by two lines ($\angle ABC$), one in each face drawn perpendicular to the edge at the same point, is called the PLANE ANGLE of the dihedral angle. Two dihedral angles are equal if their plane angles are equal. A dihedral angle is measured by its plane angle. If the plane angle is a right angle, the planes are perpendicular and form a RIGHT DIHEDRAL ANGLE. Through a given line oblique or parallel to a given plane one and only one plane can be passed perpendicular to the given plane. The line of intersection CD (Fig. 79) is the ORTHOGONAL PROJECTION of line AB upon plane P. The ANGLE BETWEEN A LINE AND A PLANE is the angle that the line (produced if necessary) makes with its orthogonal projection on the plane. This angle is the least angle which the line makes with any line in the plane.

A dihedral angle is designated by its edge and one point in each face; as dihedral angle P-BD-Q. Fig. 78.

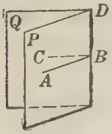

FIG. 78.

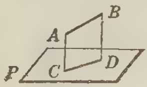

FIG. 79.

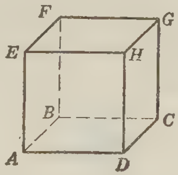

FIG. 80.

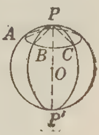

FIG. 81.

A polyhedron is a solid bounded by planes.

Figure 80 shows a common polyhedron, a CUBE, with twelve edges AB, BC, CD, etc.; six faces $ABCD$, $ABFE$, etc.; eight vertices A, B, C, D, etc., and twelve right dihedral angles E-AB-C, etc. A polyhedron is said to be CONVEX if it lies entirely on the same side of the plane of every one of its faces. A TETRAHEDRON is bounded by four triangles. The four perpendiculars erected at circumcenters of the four faces meet in a point equidistant from all vertices, which is the center of the circumscribed sphere. The four medians, joining each vertex with the center of gravity of the opposite face, meet in a point, which is the CENTER OF GRAVITY of the tetrahedron. This point is ¾ of the distance from each vertex along a median. The four altitudes meet in a point, called the ORTHOCENTER of the tetrahedron. The six planes bisecting the six dihedral angles meet in a point equidistant from all faces, the center of the inscribed sphere.

Sphere. Every plane section of a sphere is a circle. This circle is a GREAT CIRCLE when its plane passes through the center of the sphere. The POLES of a circle (P, P', Fig. 81) are extremities of the diameter of the sphere which is perpendicular to the plane of the circle. Through two points on a spherical surface not extremities of a diameter one great circle can be passed. The shortest line that can be drawn on the surface of a sphere between two points is an arc of great circle less than a semi-circumference joining those points. If two spherical surfaces intersect, their line of intersection is a circle whose plane is perpendicular to the line of centers, and whose center lies on this line.

On the surface of the earth the arcs of great circles are called GEODESICS. A SPHERICAL ANGLE is a figure formed by two arcs of great circles drawn from the same point (VERTEX), and is measured by the plane angle formed by tangents to its sides at its vertex. If planes of great circles are perpendicular, the angle is a RIGHT SPHERICAL ANGLE. A SPHERICAL POLYGON is a figure on a spherical surface bounded by three or more arcs of great circles. The sum of the angles of a spherical triangle is greater than two right angles and less than six right

angles. Two spherical polygons on the same sphere or on equal spheres are SYMMETRIC if the sides and angles of one are respectively equal to those of the other, but arranged in reverse order. Symmetric spherical polygons have equal areas.

A polyhedral angle (Fig. 82) is a figure formed by three or more RAYS, OA, OB, etc., drawn from a common origin or VERTEX O, no three of which lines lie in a plane. OA, OB, OC, etc., are called EDGES; AOB, BOC, COD, etc., FACE ANGLES; $A\text{-}OB\text{-}C$, $B\text{-}OC\text{-}D$, etc., DIHEDRAL ANGLES. A polyhedral angle is called TRIHEDRAL, TETRAHEDRAL, etc., according as it is formed by three rays, four rays, etc. The sum of two face angles of a trihedral angle is greater than the third face angle. The sum of all the face angles of any convex polyhedral angle is less than four right angles. When the edges of a polyhderal angle are produced through the vertex, a SYMMETRIC POLYHEDRAL ANGLE is formed. The face angles and dihedral angles of two symmetric polyhedral angles are equal but are arranged in reverse order.

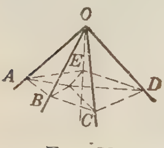

FIG. 82.

Regular solids. There are five and only five convex polyhedrons bounded by equal regular polygons. These are shown in Fig. 83, and are, from left to

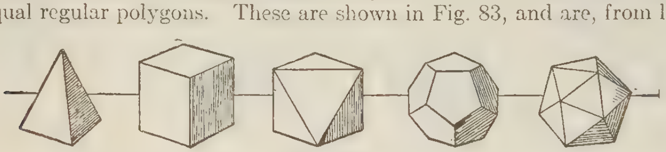

FIG. 83.

right, REGULAR TETRAHEDRON with four faces that are equilateral triangles; CUBE, with six square faces; REGULAR OCTAHEDRON, with eight faces that are equilateral triangles, REGULAR DODECAHEDRON, with twelve faces that are regular pentagons; and a REGULAR ICOSAHEDRON, with twenty faces that are equilateral triangles.

29. Areas and lengths in plane figures

Square (Fig. 84). Side $= a$, diagonal $= d$.

$d = a\sqrt{2} = 1.414a$. $a = \frac{1}{2}d\sqrt{2} = 0.707d$. $Area = a^2 = \frac{1}{2}d^2$.

Rectangle (Fig. 85). Sides $= a, b$; diagonal $= d$.

$d^2 = a^2 + b^2$. $Area = ab$.

Parallelogram (Fig. 86). Sides $= a, b$; altitude on side $a = h$; diagonals $= d_1, d_2$; acute angle at vertex $= C$.

$d_2^2 = a^2 + b^2 - 2ab \cos C\cdot$ $d_1^2 = a^2 + b^2 + 2ab \cos C$. $2(a^2 + b^2) = d_1^2 + d_2^2$. $Area = ah$.

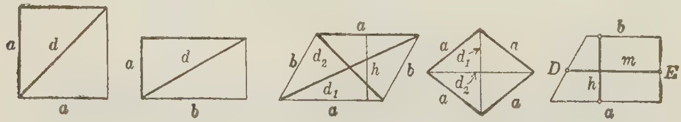

FIG. 84. FIG. 85. FIG. 86. FIG. 87. FIG. 88.

Rhombus (Fig. 87.) Each side $= a$; diagonals $= d_1, d_2$.

$d_1^2 + d_2^2 = 4a^2$. $Area = \frac{1}{2}d_1d_2$.

Trapezoid (Fig. 88). Parallel sides $= a$, b; altitude $= h$; mid-line $DE = m$.

Area $= \frac{1}{2}h(a + b) = hm$.

Triangle (Fig. 89). Sides $= a, b, c$; angles $= A, B, C$; altitude on side $a = h$; radius of inscribed circle $= r$, radius of circumscribed circle $= R$. Let $s = \frac{1}{2}(a + b + c)$.

$r = \sqrt{(s - a)(s - b)(s - c)/s}$; $R = \frac{1}{2}a/\sin A = \frac{1}{2}b/\sin B = \frac{1}{2}c/\sin C$.

Area $= \frac{1}{2}$ *base* $\times$ *altitude* $= \frac{1}{2}ah = \frac{1}{2}ab \sin C = \frac{1}{2}bc \sin A = \frac{1}{2}ca \sin B = rs = \frac{1}{4}abc/R = \sqrt{s(s - a)(s - b)(s - c)} = 2R^2 \sin A \sin B \sin C = r^2 \cot \frac{1}{2}A \cot \frac{1}{2}B \cot \frac{1}{2}C = \frac{1}{2}a^2 \sin B \sin C/\sin A$.

Length of median from vertex $A = \frac{1}{2}\sqrt{2(a^2 + b^2) - c^2}$. Length of bisector of angle $A = \sqrt{ab[(a + b)^2 - c^2]/(a + b)}$.

Equilateral triangle (Fig. 90). Side $= a$.

Altitude, $h = \frac{1}{2}a\sqrt{3} = 0.86603a$. *Area* $= \frac{1}{4}a^2\sqrt{3} = 0.43301a^2$.

Right triangle (Fig. 91). Sides $= a, b$; hypotenuse $= c$.

$c^2 = a^2 + b^2$. *Area* $= \frac{1}{2}ab = \frac{1}{2}a^2 \tan B = \frac{1}{2}a^2 \cot A = \frac{1}{4}c^2 \sin 2A$.

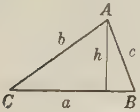

FIG. 89.

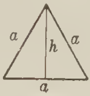

FIG. 90.

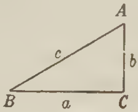

FIG. 91.

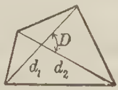

FIG. 92.

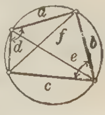

FIG. 93.

Any quadrilateral (Fig. 92). Sides $= a, b, c, d$; diagonals $= d_1, d_2$ forming angle D; line joining mid-points of diagonals $= m$.

$a^2 + b^2 + c^2 + d^2 = d_1^2 + d_2^2 + 4m^2$. *Area* $= \frac{1}{2}d_1d_2 \sin D$.

Quadrilateral inscribed in a circle (Fig. 93). Sum of opposite angles $= 180°$. Sides $= a, b, c, d$; angle formed by sides a and $b = X$; diagonals $= e, f$.

$ac + bd = ef$. Let $s = \frac{1}{2}(a + b + c + d)$.

Area $= \sqrt{(s - a)(s - b)(s - c)(s - d)} = (ab + cd) \sin X$.

Regular polygons (Fig. 94). Side $= a$, number of sides $= n$.

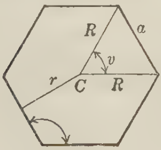

FIG. 94.

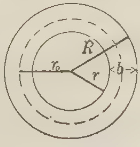

FIG. 95.

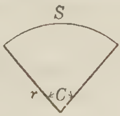

FIG. 96.

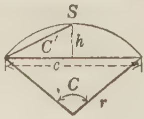

FIG. 97.

Vertex angle $= 360°(n - 2)/n$. Central angle (as v) $= 360°/n$. Radius of inscribed circle $= r = \frac{1}{2}a \cot \frac{1}{2}v = \frac{1}{2}a \tan \frac{1}{2}A$. Radius of circumscribed circle $= R = \frac{1}{2}a/\sin \frac{1}{2}v = \frac{1}{2}a/\cos \frac{1}{2}A$. *Area* $= \frac{1}{2}nar = a^2(\frac{1}{4}n \cot \frac{1}{2}v) = a^2k$. Values of k are given in following table:

n	3	4	5	6	7	8	9	10	11	12
k	0.433	1.000	1.720	2.598	3.634	4.828	6.182	7.694	9.366	11.196

Circle. Radius $= r$, diameter $= d$.

Ratio of circumference to diameter $= \pi = 3.1415927$. Circumference $= 2\pi r = \pi d$. *Area* $= \pi r^2 = \frac{1}{4}\pi d^2 = 0.7854d^2$. See Table 6, p. 1460.

Circular ring (or ANNULUS). (Fig. 95.) Outer radius $= R$, inner radius $= r$.

Mean radius $= r_0 = \frac{1}{2}(R + r)$; width $= b = R - r$. *Area* $= \pi(R^2 - r^2) = \pi(R + r)(R - r) = 2\pi r_0 b$.

Circular arc (Fig. 96). Radius $= r$, length of arc $= S$, central angle $= C$.

$S = rC$ (when C is expressed in radians) $= \pi rC/180 = 0.01745rC$ (when C is expressed in degrees). See Tables 10–13, p. 1466. If chord of arc (Fig. 97) $=$ S, and chord of half the arc $= c'$, then $S = 2c' + \frac{1}{3}(2c' - c)$, approximately (Huyghen's formula).

Circular sector (Fig. 96). *Area* $= \frac{1}{2}Sr = \frac{1}{2}r^2C$ (when C is expressed in radians) $= \pi r^2C/360$ (when C is expressed in degrees) $= 0.008727r^2C$.

Circular segment (Fig. 97). Height of segment $= h$, chord $= c$, chord of half arc $= C'$.

$C'^2 = 2hr$; $c = 2r \sin \frac{1}{2}C$; $h = r(1 - \cos \frac{1}{2}C)$, $r = (\frac{1}{4}c^2 + h^2)/2h$. *Area* $= \frac{1}{2}r^2(C - \sin C)$, (angle C in radians) $= \frac{1}{2}(rS + ch - cr)$. Approximate formula: *Area* $= \frac{4}{3}h^2\sqrt{2r/h - 0.608}$. See Table 9, p. 1464.

Parabolic segment (Fig. 98). Chord $= c$, height $= h$, arc $= S$.

$$Area = \tfrac{2}{3}ch. \quad S = \tfrac{1}{2}\sqrt{c^2 + 16h^2} + \frac{c^2}{8h} \text{ Nap log } (4h + \sqrt{c^2 + 16h^2})/c.$$

Area between two chords c, C, parallel and at a distance d apart $= \frac{2}{3}d\,\dfrac{C^3 - c^3}{C^2 - c^2}$.

Ellipse (Fig. 99). Semi-axes, major $= a$, minor $= b$.

Area between BB' *and* PP' $= xy + ab \sin^{-1} x/a$. *Area of sector* AOP $= \frac{1}{2}ab \cos^{-1} x/a$. *Area of ellipse* $= \pi ab$. *Perimeter of ellipse* $= 4aE$. Values of E for $t = b/a$ are as follows:

t	0	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9	1.0
E	1.000	1.016	1.051	1.097	1.151	1.211	1.276	1.346	1.418	1.493	1.571

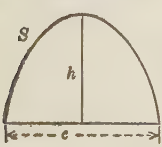

FIG. 98.

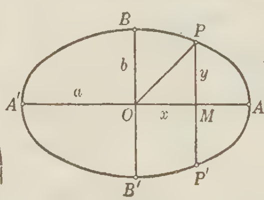

FIG. 99.

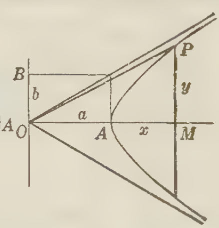

FIG. 100.

Hyperbola (Fig. 100). Semi-axes, transverse $= a$, conjugate $= b$.

Area $AMP = \frac{1}{2}xy - \frac{1}{2}ab$ Nap log $(x/a + y/b)$. *Area* $OAP = \frac{1}{2}ab$ Nap log $(x/a + y/b) = \frac{1}{2}abu$, where $x = a \cosh u$.

Cycloid. (See Fig. 177, p. 1411.) Radius of rolling circle $= a$.

Length of arc $OP = 4a(1 - \cos \frac{1}{2}\theta)$. Length of entire arc $OMN = 8a$.

Area between arc OMN and base $OX = 3\pi a^2 =$ three times area of rolling circle.

Epicycloid. (See Fig. 179, p. 1412.) Arc $AP = 4r\,(R + r)\,(1 - \cos (R\theta/2r))/R$. *Area* $AOP = [r(R + r)(R + 2r)](R\theta/r - \sin R\theta/r)/2R$.

Hypocycloid. (See Fig. 180, p. 1412.) Formulas for arc and area are the same as for epicycloid with sign of r changed.

Catenary. (See Fig. 184, p. 1413.) Arc $BP = a \sinh x/a = \sqrt{y^2 - a^2}$ where x, y, are co-ordinates of P. *Area* $OMPB = a^2 \sinh x/a = a\sqrt{y^2 - a^2}$.

Spiral of Archimedes. (See Fig. 185, p. 1413.) Arc $OP = \frac{1}{2}a[\theta\sqrt{1 + \theta^2} + \text{Nap log}\,(\theta + \sqrt{1 + \theta^2})]$, θ in radians.

Simpson's rule for approximate measure of an area (Fig. 101). Divide the area by equidistant parallel lines into an even number n of strips each of width b, and denote the lengths of the parallel sides of these strips successively by $y_0, y_1, y_2, y_3 \ldots, y_n$. Then an approximate value for the area is, *Area* $= \frac{1}{3}b(y_0 + 4y_1 + 2y_2 + 4y_3 + 2y_4 + \ldots + 4y_{n-1} + y_n)$, or

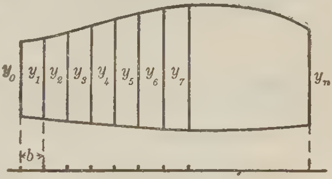

FIG. 101.

$$= \tfrac{1}{3}b[(y_0 + y_n) + 4(y_1 + y_3 + y_5 + \ldots y_{n-1}) + 2(y_2 + y_4 + y_6 + \ldots y_{n-2})].$$

Increasing the number of strips gives a closer approximation.

30. Surfaces and volumes of solids

Prism (Fig. 102). Perimeter of a plane section $FGHKL$ cutting all edges at right angles (right section) $= c$; length of lateral edge $AA' = l$; altitude (perpendicular distance between upper and lower bases) $= h$, area of base $ABCDE = B$.

Lateral surface $= cl$. *Volume* $= Bh$.

Right-circular cylinder (Fig. 64). Diameter of base $= d$, altitude $= h$. *Lateral surface* $= \pi dh$. *Total surface* $= \pi d(h + \frac{1}{2}d)$. *Volume* $= \pi d^2h/4$.

Truncated right-circular cylinder (Fig. 103). Diameter of circular base $= d$, arithmetic mean of longest and shortest elements $= h (= \frac{1}{2}(AB + CD))$.

Lateral surface $= \pi dh$. *Volume* $= \pi d^2h/4$.

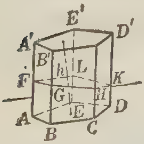

FIG. 102.

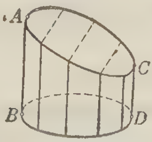

FIG. 103.

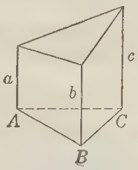

FIG. 104.

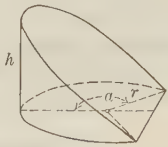

FIG. 105.

Truncated triangular prism (Fig. 104). Area of base $ABC = B$, lengths of edges $= a, b, c$.

Volume $= \frac{1}{3}B(a + b + c)$.

Ungula of right-circular cylinder (Fig. 105). Base is a circular segment with central angle $2a$ (radians) and area B. (See Art. 29.)

Lateral area $= hr(2 \sin a - a \cos a)/(1 - \cos a)$. *Volume* $= h(\frac{2}{3}r^2 \sin^3 a - B \cos a)/(1 - \cos a)$.

Hollow right-circular cylinder. Outer and inner diameters = D, d, altitude = h, thickness = t.

Volume $= \pi ht(D + d)/2$.

Regular pyramid (Fig. 75). Base $ABCDE$ is a regular polygon, lateral faces are equal isosceles triangles. Side of base = a, area of base = B (see Art. 29), altitude of a lateral face (slant height of pyramid) = s (= VF), altitude of pyramid (= VO) = h.

Lateral area $= \frac{1}{2}nas$. *Volume* $= \frac{1}{3}Bh$.

Right-circular cone (Fig. 74). Radius of base = r (= OB), slant height $VB = s$, altitude = $h = VO$.

$s = \sqrt{h^2 + r^2}$. *Lateral area* $= \pi rs$. *Total area* $= \pi r(s + r)$. *Volume* $= \frac{1}{3}\pi hr^2$.

Frustum of a regular pyramid (Fig. 76). Altitude of a lateral face (slant height of frustum FF') = s, perimeter of bases = p, P; areas of bases = b, B; altitude of frustum = $h = OO'$.

Lateral area $= \frac{1}{2}s(p + P)$. *Volume* $= \frac{1}{3}h(B + b + \sqrt{Bb})$.

Frustum of right-circular cone (Fig. 77). Slant height = s, radii of bases = r_1, r_2, altitude = $h = OO'$

$s = \sqrt{h^2 + (r_2 - r_1)^2}$. *Lateral area* $= \pi s(r_1 + r_2)$. *Total area* $= \pi(r_1^2 + r_2^2 + s(r_1 + r_2))$. *Volume* $= \frac{1}{3}\pi h(r_1^2 + r_2^2 + r_1r_2)$.

Any pyramid or cone. Altitude = h, area of base = B.

Volume $= \frac{1}{3}Bh$.

Frustum of any pyramid or cone. Altitude = h, areas of bases = b, B.

Volume $= \frac{1}{3}h(B + b + \sqrt{Bb})$.

Regular polyhedrons (see Art. 28). Edge = a.

	Tetrahedron	*Cube*	*Octahedron*	*Dodecahedron*	*Icosahedron*
Area.	$1.7321a^2$	$6a^2$	$3.4641a^2$	$20.646a^2$	$8.6603a^2$
Volume.	$0.1179a^3$	a^3	$0.4714a^3$	$7.6631a^3$	$2.1817a^3$

Sphere. Radius = r, diameter = d.

Area of surface $= 4\pi r^2 = \pi d^2 =$ *four great circles*. Volume $= \frac{4}{3}\pi r^3 = \frac{1}{6}\pi d^3$. Table 7.

Spherical polygon (see Art. 28.) Sum of angles in degrees = S, number of sides = n. Spherical excess $= E = S - (n - 2)180$ (in degrees).

Area $= \pi r^2E/180$.

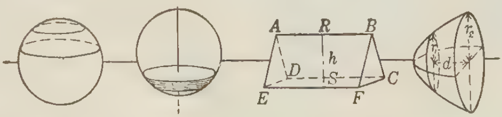

FIG. 106. FIG. 107. FIG. 108. FIG. 109.

Zone (Fig. 106) is a portion of a spherical surface included between two parallel plane sections. Altitude = h (perpendicular distance between parallel planes), radius of sphere = r.

Area of zone $= 2\pi rh$ (product of circumference of a great circle and altitude of zone).

Spherical segment (Fig. 107) is the portion of sphere included between two parallel plane sections called bases. Radii of bases = b, B; altitude of segment = h (perpendicular distance between bases).

Volume $= \frac{1}{2}\pi h(B^2 + b^2 + \frac{1}{3}h^2)$.

Wedge (Fig. 108). Base $DEFC$ is a rectangle, $CF = b$, $EF = L$, edge $AB = l$, at perpendicular distance $RS = h$ from base.

Volume $= \frac{1}{6}bh(2L + l)$.

Prismatoid. Bases are polygons in parallel planes, areas = b, B. Lateral faces are trapezoids or triangles whose vertices coincide with certain vertices of the bases. Altitude = h (perpendicular distance between bases), area of plane section midway between bases = m.

Volume $= \frac{1}{6}h(b + B + 4m)$.

Segment of paraboloid (Fig. 109). Radii of bases = r_1, r_2; altitude = d.

Volume $= \frac{1}{2}\pi d(r_1^2 + r_2^2)$.

Ellipsoid (Fig. 110). Semi-axes = a, b, c.

Volume $= \frac{4}{3}\pi abc$.

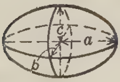

Fig. 110.

Fig. 111.

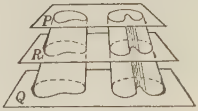

Fig. 112.

Theorems of Pappus. (1) If a closed plane figure is revolved about an exterior axis in its own plane, the volume of the solid generated equals the product of the area of the plane figure by the length of the circular path described by its center of gravity. (2) If a plane curve is revolved about an exterior axis in its plane, the area of the surface generated equals the product of the arc of the curve by the length of the circular path described by its center of gravity. These theorems are useful in determining centers of gravity when other quantities involved are known, and also in calculating areas and volumes when centers of gravity are given.

Torus (ANCHOR RING). (Fig. 111.) Application of preceding Theorems of Pappus gives the following results:

Area $= 2\pi a \times 2\pi b = 4\pi^2 ab$. *Volume* $= \pi a^2 \times 2\pi b = 2\pi^2 a^2 b$.

Cavalieri's theorem (Fig. 112). If two solids are included between a pair of parallel planes, and if the two sections cut from them by any plane parallel to the including planes are equal in area, then the volumes of the solids are equal.

TRIGONOMETRY

31. Trigonometric functions of an acute angle

In Fig. 113 take a point B on side AD of angle A, and draw BC perpendicular to side AE, forming the right triangle BAC. In this triangle, for

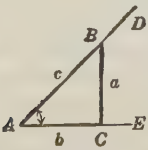

Fig. 113.

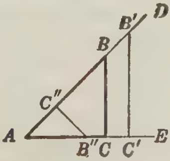

Fig. 114.

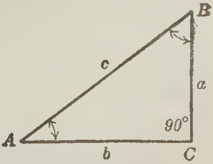

Fig. 115.

angle A, $BC(=a)$ is called OPPOSITE SIDE, and $AC\ (=b)$, ADJACENT SIDE. The trigonometric functions of A are sine of A, cosine of A, tangent of A, cotangent of A, secant of A, and cosecant of A, written, respectively sin A, cos A, tan A, cot A, sec A, csc A, and defined as equal to ratios as follows:

$$\sin A = \frac{\text{opposite side}}{\text{hypotenuse}} = \frac{a}{c}, \qquad \csc A = \frac{\text{hypotenuse}}{\text{opposite side}} = \frac{c}{a},$$

$$\tan A = \frac{\text{opposite side}}{\text{adjacent side}} = \frac{a}{b}, \qquad \cot A = \frac{\text{adjacent side}}{\text{opposite side}} = \frac{b}{a},$$

$$\cos A = \frac{\text{adjacent side}}{\text{hypotenuse}} = \frac{b}{c}, \qquad \sec A = \frac{\text{hypotenuse}}{\text{adjacent side}} = \frac{c}{b}.$$

Sine and cosine of A are called CO-FUNCTIONS of each other, as also are tangent, and cotangent, secant and cosecant.

Functions of A are independent of the position of B on AD. In fact, by plane geometry (Art. 25), in Fig. 114, when $B'C'$ is perpendicular to AE, and $B''C''$ perpendicular to AD, $BC/AB = B'C'/AB' = B''C''/AB''$. That is, sin A equals any one of these ratios. Any one of the triangles ABC, $AB'C'$, $AB''C''$ might be used to give trigonometric functions of A.

In the right triangle ABC (Fig. 115), angles A and B are COMPLEMENTARY angles (sum $= 90°$). Sin $A = \cos B$, $\tan A = \cot B$, $\sec A = \csc B$, $\cos A = \sin B$, $\cot A = \tan B$, $\csc A = \sec B$. Any function of an angle equals the corresponding co-function of the complementary angle.

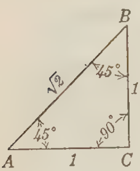

FIG. 116.

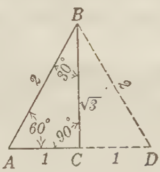

FIG. 117.

Functions of 30°, 45° and 60°. In Fig. 116, triangle ABC is an ISOSCELES RIGHT TRIANGLE, $AC = BC$, angle $A =$ angle $B = 45°$, sides AC and BC are of unit length and $AB = \sqrt{2}$. In Fig. 117, triangle ABD is equilateral with sides 2 units in length, each angle is 60°. In right triangle ABC, $A = 60°$, $B = 30°$, $BC = \sqrt{3}$.

Angle	Sin	Cos	Tan	Cot	Sec	Csc
30°	1/2	$\sqrt{3}/2$	$\sqrt{3}/3$	$\sqrt{3}$	$2\sqrt{3}/3$	2
45°	$\sqrt{2}/2$	$\sqrt{2}/2$	1	1	$\sqrt{2}$	$\sqrt{2}$
60°	$\sqrt{3}/2$	1/2	$\sqrt{3}$	$\sqrt{3}/3$	2	$2\sqrt{3}/3$

In addition to the six functions defined above, the following are also used. Versine of A = vers $A = 1 - \cos A$. Coversine of A = covers $A = 1 - \sin A$. Haversine of A = havers $A = \frac{1}{2}(1 - \cos A)$.

Tables for trigonometric functions. Natural values. Tables 14, 15, pp. 1468-1471, give values of sine, cosine, tangent and cotangent for all angles less than 90° at 10-minute intervals. (For 90°, see Art. 38.) For intermediate angles interpolation may be used, with the caution that sine and tangent increase as angle increases, while cosine and cotangent decrease as angle increases. Values of sine and tangent are under captions at the top of pages; of cosine and cotangent above captions at the bottom of pages.

Examples. Sine 25° 12′ = 0.4258. Cos 25° 12′ = 0.9048. Tan 36° 18′ = 0.7346 = tan 36° 20′ *minus* the correction for 2′ (= 9 units). Cot 26° 17′ = 2.024 = cot 26° 20′

plus the correction for 3′ (= 4 units). For values of secant and cosecant, use the relations secant = 1/cosine, cosecant = 1/sine and Table 5 (p. 1456).

Natural values by slide rule. See Art. 5.

Tables of logarithms of trigonometric functions. Tables 18, 19.

Annex − 10 to the given tabular values. Interpolation will be inaccurate for logarithmic sines and tangents of angles less than 6°, and for cosines and cotangents of angles greater than 83°. Five- or more-place tables should be consulted for such angles. In interpolation, follow the directions given above for natural values.

Example. Log sin 28° 32′ = 9.6792 − 10. Log cot 19° 38′ = 0.4477.

Relations between functions. $\sin^2 A + \cos^2 A = 1$. $\sec^2 A = 1 + \tan^2 A$. $\csc^2 A = 1 + \cot^2 A$. $\sin A = 1/\csc A$. $\tan A = 1/\cot A$. $\sec A = 1/\csc A$.

Expressions for sin, cos, and tan in terms of each of the other functions.

$$\sin A = \sqrt{1 - \cos^2 A} = \tan A/\sqrt{1 + \tan^2 A} = 1/\sqrt{1 + \cot^2 A}$$
$$= \sqrt{\sec^2 A - 1}/\sec A = 1/\csc A.$$

$$\tan A = \sin A/\sqrt{1 - \sin^2 A} = \sqrt{1 - \cos^2 A}/\cos A = 1/\cot A$$
$$= \sqrt{\sec^2 A - 1} = 1/\sqrt{\csc^2 A - 1}.$$

$$\cos A = \sqrt{1 - \sin^2 A} = 1/\sqrt{\tan^2 A + 1} = \cot A/\sqrt{\cot^2 A + 1}$$
$$= 1/\sec A = \sqrt{\csc^2 A - 1}/\csc A.$$

32. Functions of an obtuse angle

Line definitions. In Fig. 118, the ratio definitions of the functions of angle AOP (Art. 31) are replaced by line definitions as marked, the unit of length being the radius of the circle (unit circle). For an OBTUSE ANGLE (angle between 90° and 180°), the functions are defined for angle AOP as in Fig. 119, with the following conventions (in both figures) as to positive and negative: Horizontal lines OQ (= cosine) and BC (= cotangent) to the right of the vertical diameter (Fig. 118) are positive, to left (Fig. 119) are negative. Vertical line as PQ (= sine) above horizontal diameter is positive, AT (= tangent) below (Fig. 119) is negative. OC (= cosecant) extending *along* terminal side OP, is positive, while OT (= secant), measured along OP *produced* (Fig. 119) is negative. For an obtuse angle, the sine and cosecant are positive, and the other functions negative. To find the natural values of the functions of an obtuse angle, write the angle in one of the forms 90° + x or 180° − x, where x is less than 90°, and use the following formulas:

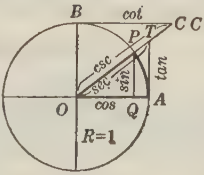

FIG. 118.

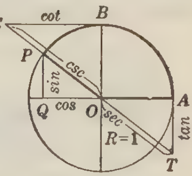

FIG. 119.

A	Sin A	Cos A	Tan A	Cot A	Sec A	Csc A
90° + x	cos x	− sin x	− cot x	− tan x	− csc x	sec x
180° − x	sin x	− cos x	− tan x	− cot x	− sec x	csc x

Example. Find sin 108°. Write 108° = 90° + 18°, or 180° − 72°. Hence sin 108° = cos 18° = sin 72° = 0.9511. Find tan 128°. Write 128° = 90° + 38°, or 180° − 52°. Then tan 128° = − cot 38° = − tan 52° = − 1.2799.

33. Oblique triangles. Formulas

Sides a, b, c, angles A, B, C, angle A opposite side a, etc.

Law of sines. $a/\sin A = b/\sin B = c/\sin C$. (See also Art. 29.)

Law of tangents. $(a + b)/(a - b) = \tan \frac{1}{2}(A + B)/\tan \frac{1}{2}(A - B)$.

Law of cosines. $a^2 = b^2 + c^2 - 2bc \cos A$. $b^2 = c^2 + a^2 - 2ca \cos B$. $c^2 = a^2 + b^2 - 2ab \cos C$. $\operatorname{Cos} A = (b^2 + c^2 - a^2)/2bc$. $\operatorname{Cos} B = (c^2 + a^2 - b^2)/2ac$. $\operatorname{Cos} C = (a^2 + b^2 - c^2)/2ab$.

If $s = \frac{1}{2}(a + b + c)$ and $r = \sqrt{(s - a)(s - b)(s - c)/s}$, $\sin \frac{1}{2} A = \sqrt{(s - b)(s - c)/bc}$. $\operatorname{Cos} \frac{1}{2}A = \sqrt{s(s - a)/bc}$, $\tan \frac{1}{2} A = r/(s - a)$.

Area $= \sqrt{s(s - a)(s - b)(s - c)} = \frac{1}{2}bc \sin A = \frac{1}{2}a^2 \sin B \sin C/\sin A$.

$\operatorname{Sin} A = 2\ \mathit{Area}/bc$. $\operatorname{Sin} B = 2\ \mathit{Area}/ca$. $\operatorname{Sin} C = 2\ \mathit{Area}/bc$.

Sides. $a = b \cos C + c \cos B$. $b = \cos A + a \cos C$. $c = a \cos B + b \cos A$.

Sum of sines. $\operatorname{Sin} A + \sin B + \sin C = 4 \cos \frac{1}{2}A \cos \frac{1}{2}B \cos \frac{1}{2}C$.

Sum of cosines. $\operatorname{Cos} A + \cos B + \cos C = 4 \sin \frac{1}{2}A \sin \frac{1}{2}B \sin \frac{1}{2}C + 1$.

Sum of tangents. $\operatorname{Tan} A + \tan B + \tan C = \tan A \tan B \tan C$.

Squares of sines. $\operatorname{Sin}^2 A + \sin^2 B + \sin^2 C = 2 \cos A \cos B \cos C + 2$.

Products of cotangents. $\operatorname{Cot} A \cot B + \cot B \cot C + \cot C \cot A = 1$.

Sines of twice the angles. $\operatorname{Sin} 2A + \sin 2B + \sin 2C = 4 \sin 2A \sin 2B \sin 2C$.

34. Solution of plane triangles

A triangle has six parts, the sides a, b, c, and angles A, B, C, angle A being opposite a, etc. Certain necessary relations exist between the parts, as that the sum of the angles $= 180°$, the sum of two sides is greater than the third side, and the greater side is opposite the greater angle. With these restrictions, a triangle can be determined when one side and two other parts are given. The determination of unknown parts is called SOLVING THE TRIANGLE. The formulas given below for the usual cases will give the unknown parts by substitution of numerical data, using tables of natural values and computing by slide rule, or using logarithms and tables.

Right triangles

(Fig. 113). $\angle A + \angle B = 90°$. $\angle C = 90°$.

Given an angle and opposite side, as A a. Unknowns, B, c, b. Formulas: $B = 90° - A$; $c = a/\sin A$, $b = a \cot A$.

Given an angle and adjacent side, as A, b. Unknowns, B, a, c. Formulas: $B = 90° - A$. $a = b \tan A$. $c = b/\cos A = b \sec A$

Given two sides a, b. Formulas: $\tan A = a/b$. $B = 90° - A$. $c = \sqrt{a^2 + b^2} = a/\sin A = a \csc A$.

Given a side, as a, **and hypotenuse** c. Formulas: $\sin A = a/c$. $B = 90° - A$. $b = \sqrt{(c + a)(c - a)}$.

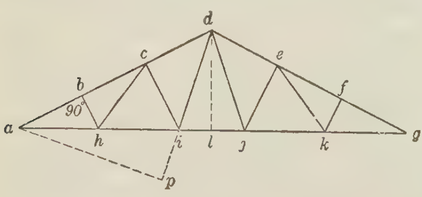

FIG. 120.

Example. In the roof truss (Fig. 120), with normal struts bh, ci, etc., the span $= ag = 60$ ft., rise $= dl = 15$ ft., find angle dil, and length of perpendicular ap let fall from a upon member di produced.

Solution. In the right triangle adl, $al = 30$ ft., $dl = 15$ ft. Hence $\tan \alpha = dl/al = 0.5$, and angle $\alpha = 26° 34'$ (Table 15). $ad = al \sec \alpha = 30 \times 1.118 = 33.54$. In the right

triangle *aci*, $ac = \frac{2}{3}\ ad = 22.36$. $ai = ac \sec a = 22.36 \times (1.118) = 25$. In right triangle *dil*, $il = al - ai = 5$, $dl = 15$. $\tan \angle dil = 3$. Angle $dil = 71° 34'$. In right triangle *aip*, $ai = 25$, angle $aip = 71° 34'$ (being equal to angle *dil*). $ap = ai \sin \angle aip = 25 \times 0.9487 = 23.72$. *Ans.*

Oblique triangles

Before solving, it is well to construct a triangle with the given parts to scale, using a protractor for laying off the given angle or angles. The unknown parts may then be measured and estimated.

Given one side and any two angles, as a, A, B. $C = 180° - (A + B)$. By the law of sines (Art. 33) $b = a \sin B/\sin A$ and $c = a \sin C/\sin A$.

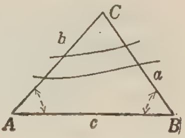

FIG. 121.

Example. A and B are stations 1800 ft. apart on one side of a river, C a station on the opposite side. To determine the distances from A and B to C, angles CAB and CBA are measured and found to be $48° 30'$, and $54° 24'$, respectively. Find AC and BC.

Solution. (Fig. 121.) A side c and two angles are given. $c = 1800$, angle $CAB = A = 48° 30'$, angle $CBA = B = 54° 24'$. Hence angle $C = 180° - (48° 30' + 54° 24') = 77° 6'$.

$a = 1800 \sin 48° 30'/\sin 77° 6'$. $\log a = \log c + \log \sin A - \log \sin c$.

$b = 1800 \sin 54° 24'/\sin 77° 6'$. $\log b = \log c + \log \sin B - \log \sin C$.

c	log 1800	= 3.2553	c	log 1800	= 3.2553
A	log sin 48° 30′	= 9.8745	B	log sin 54° 24′	= 9.9101
	Sum	= 3.1298		Sum	= 3.1654
C	log sin 77° 6′	= 9.9889	C	log sin 77° 6′	= 9.9889
a	log 1383	= 3.1409	b	log 1501	= 3.1765

Given two sides and included angle, as a, b, C. Let the greater of the given sides be a. Then $\frac{1}{2}(A + B) = 90° - \frac{1}{2}C$. By Art. 33 (law of tangents) $\tan \frac{1}{2}(A - B) = (a - b) \cot \frac{1}{2}C/(a + b)$, giving $\frac{1}{2}(A - B)$. Then $A = \frac{1}{2}(A + B) + \frac{1}{2}(A - B)$. $B = \frac{1}{2}(A + B) - \frac{1}{2}(A - B)$. $c = a \sin C/\sin A$. *Check* by the law of sines (Art. 33).

Alternative method. Use the law of cosines (Art. 33) to find the unknown side. $c^2 = a^2 + b^2 - 2ab \cos C$. $\sin B = b \sin C/c$. $(B < 90°)$. $A = 180° - (B + C)$. This method is useful when the third side only is required.

Formulas for sin B and sin A, using the law of sines do not determine these angles without ambiguity, since an angle (x) and its supplement $(180° - x)$ have the same sine (Art. 32). But it $b < a$, angle B must be acute. From $A = 180° - (B + C)$, angle A may be found and the result checked by the law of tangents.

Example. Two stations A and B on opposite sides of a mountain are both visible from a third station C. Distances AC and BC are 11.5 mi. and 9.4 mi., respectively; angle $ACB = 59° 31'$. Find the distance from A to B.

Solution. Two sides a, b, and the included angle C are given. Side c is required. $a = 9.4$, $b = 11.5$, $C = 59° 31'$.

$$c = \sqrt{a^2 + b^2 - 2ab \cos C} = \sqrt{88.36 + 132.25 - 109.68} = \sqrt{110.9} = 10.53 \text{ mi.}$$

Given three sides, a, b, c.

$$s = \tfrac{1}{2}(a + b + c). \quad r = \sqrt{(s - a)(s - b)(s - c)/s}.$$

$$\tan \tfrac{1}{2}A = \frac{r}{s - a}, \quad \tan \tfrac{1}{2}B = \frac{r}{s - b}, \quad \tan \tfrac{1}{2}C = \frac{r}{s - c}.$$

Check. $A + B + C = 180°$.

Alternative method. $\cos A = (b^2 + c^2 - a^2)/2bc$. If $b < a$, find B (one acute angle) from $\sin B = b \sin A/a$. $C = 180° - (A + B)$.

Given two sides and angle opposite one of them, as, a, b, A.

(1) *There are two solutions*, if A is acute and the value of a lies between b and $b \sin A$, as in Fig. 122. Here $b \sin A = CP$, and triangles ACB' and ACB are both solutions. To see if two solutions exist, examine the given data and calculate $b \sin A$. If $a < b$ and $> b \sin A$, there are two solutions. Solve triangle ABC by the formulas $\sin B = b \sin A/a$; angle $ACB = 180° - (A + B)$; $AB = a \sin \angle ACB/\sin A$. Then in triangle $AB'C$, angle $AB'C = 180° - B$; angle $ACB' = 180° - A - \angle AB'C$; $AB' = a \sin \angle ACB'/\sin A$.

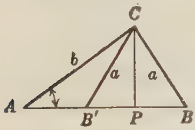

FIG. 122.

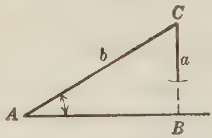

FIG. 123.

(2) *There is no solution* if A is acute and the value of a is less than $b \sin A$, because the side opposite A is not long enough to reach the opposite side, *i.e.*, $a < CB$. (Fig. 123.)

(3) *There is one solution* in all other cases. Solve as in triangle ABC above.

35. Angles of any magnitude

The notion of magnitude of an angle must be generalized for purposes of trigonometric analysis. The general concept may be stated thus: An angle is considered as generated by a line (GENERATING LINE) which first coincides with one side (INITIAL SIDE) of the angle, then revolves about the vertex and finally coincides with other side (TERMINAL SIDE). An angle generated by counterclockwise rotation is POSITIVE (Fig. 124a), by clockwise rotation, NEGATIVE (Fig. 124b). The generating line may be regarded as making any number of complete revolutions before coinciding finally with the terminal side, hence the magnitude of an angle may be as large as we choose.

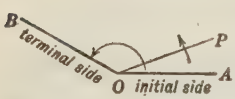

FIG. 124a.

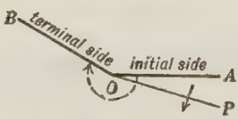

FIG. 124b.

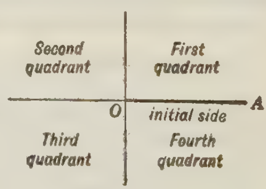

FIG. 125.

Four quadrants. It is customary to divide the plane about the vertex of an angle into four quadrants by drawing two mutually perpendicular lines through the vertex, one of these lines (OA) coinciding with the initial side of all angles (Fig. 125). An angle is said to lie in a certain quadrant when its terminal side falls in that quadrant. Angles between 0° and 90° lie in first quadrant, between 90° and 180° in second quadrant, between 180° and 270° in third quadrant, between 270° and 360° in fourth quadrant. For *negative* angles, those between 0° and $-90°$ lie in fourth quadrant, between $-90°$ and $-180°$ in third quadrant, between $-180°$ and $-270°$ in second quadrant, between $-270°$ and $-360°$ in first quadrant. Addition to or subtraction from an angle of multiples of 360° gives an angle of different magnitude but the same terminal side, hence in the same quadrant.

36. Angle measurement

Two systems of measuring angles are in use in engineering.

Degree measure. The unit angle is one DEGREE, viz., an angle at the center of a circle whose intercepted arc equals 1/360th of the circumference.

Circular measure. The unit angle is one RADIAN, viz.: an angle at the center of a circle intercepting an arc equal in length to the radius of the circle. (Fig. 126.) For any central angle in a circle, the number of radians in the angle = *length of intercepted arc/length of radius.*

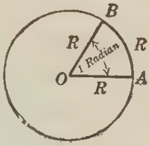

FIG. 126.

Relation between unit angles. 1 degree = 0.01745 radian = $\pi/180$ radian. 1 radian = 57.2957 degrees = $180/\pi$ degrees. 90° = $\pi/2$ radians. 180° = π radians. 270° = $3\pi/2$ radians. 360° = 2π radians (π = 3.14159265). See also Tables 10 to 13, inclusive.

37. Functions of an angle in any quadrant

In the first and second quadrants, functions are defined by the lengths of lines in the unit circle as in Figs. 118 and 119, in the third and fourth quadrants as in Figs. 127 and 128, respectively. For conventions as to positive and negative lines, see Art. 32. The rule for signs of functions of angles in different quadrants is shown in Fig 129. To write down the numerical

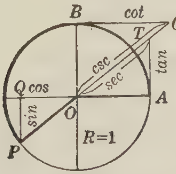

FIG. 127.

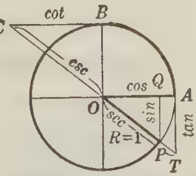

FIG. 128.

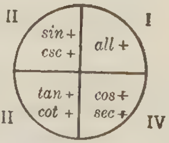

FIG. 129.

values of functions of an angle of any magnitude, express the angle in degrees, and, if necessary, add or subtract multiples of 360° until the magnitude lies between 0° and 360°. Then observe in what quadrant the angle lies. If in the first quadrant, the functions are given by Tables 14 and 15. If in the second quadrant, proceed as in Art. 32.

Third-quadrant angles. Write the magnitude of the angle, which is between 180° and 270°, in the form $180° + x$, or $270° - y$, where x and y are between 0° and 90°, and use the following formulas:

A	Sin A	Cos A	Tan A	Cot A	Sec A	Csc A
$180° + x$	$-\sin x$	$-\cos x$	$\tan x$	$\cot x$	$-\sec x$	$-\csc x$
$270° - y$	$-\cos y$	$-\sin y$	$\cot y$	$\tan y$	$-\csc y$	$-\sec y$

Fourth-quadrant angles. Express the angle, which now lies between 270° and 360°, in either of the forms $270° + y$ or $360 - x$, where x and y are between 0° and 90°, and use the following formulas:

A	Sin A	Cos A	Tan A	Cot A	Sec A	Csc A
$360° - x$	$-\sin x$	$\cos x$	$-\tan x$	$-\cot x$	$\sec x$	$-\csc x$
$270° + y$	$-\cos y$	$\sin y$	$-\cot y$	$-\tan y$	$\csc y$	$-\sec y$

Examples. To find tan 985° 15′. Reduce to an angle between 0° and 360° by subtracting $2 \times 360°$. $985° 15' - 720° = 265° 15'$, which is an angle in the third quadrant. $265° 15' = 180° + 85° 15' = 270° - (4° 45')$. Tan 265° 15′ = tan 85° 15′ = cot 4° 15′ = 13.46. Hence tan 985° 15′ = 13.46. *Ans.*

To find csc (− 385° 20′). Adding 720°, $720° - 385° 20' = 334° 40'$, which is an angle in the fourth quadrant. $334° 40' = 360° - 25° 20' = 270° + 64° 40'$. Csc 334° 40′ = − csc 25° 20′ = − sec 64° 40′ = − 2.337. Hence csc (− 385° 20′) = − 2.337.

Relations between functions of positive and negative angles which are numerically equal are: $\sin(-A) = -\sin A$; $\cos(-A) = \cos A$; $\tan(-A) = -\tan A$; $\cot(-A) = -\cot A$; $\sec(-A) = \sec A$; $\csc(-A) = -\csc A$.

38. Functions of 0°, 90°, 180°, 270°, 360°

Angle	Sin	Cos	Tan	Cot	Sec	Csc
0° and 360°	0	1	0	∞	1	∞
90°	1	0	∞	0	∞	1
180°	0	− 1	0	∞	− 1	∞
270°	− 1	0	∞	0	∞	− 1

39. Angles for which one function has a given value

All angles whose magnitude is expressible as $n \times 180° + (-1)^n \times A$ where n is any integer, positive or negative, and A is expressed in degrees, have the same sine and cosecant as A. (In radians, $\pi n + (-1)^n A$.) If expressible as $n \times 180° + A$, they have the same tangent and cotangent as A. (In radians, $\pi n + A$.) All angles expressible as $n \times 360° \pm A$ have the same secant and cosine as A. (In radians, $\pi n + A$.)

Example. Solve $2 \sin A - \cos A = 0$ for A. Transposing $\cos A$ to the right-hand member and dividing both members by $\cos A$ gives $2 \sin A/\cos A = 1$, or $\tan A = \frac{1}{2}$. The value of A between 0° and 90° satisfying this equation is $A = 26° 34'$. (Table 15.) Hence the solution is: $n \times 180° + 26° 34'$, where n is any integer, positive or negative. Angles between 0° and 360° satisfying the equation are 26° 34′, and 206° 34′ ($n = 1$).

40. Graphs of trigonometric functions

Graphs of trigonometric functions are drawn by plotting values of the angle as abscissas and values of the function as ordinates. See Figs. 130–133. Points on the X-axis corresponding to angles for which the function is zero or infinity, are marked in radians. Graphs of $\sin x$ and $\csc x$ are obtained from

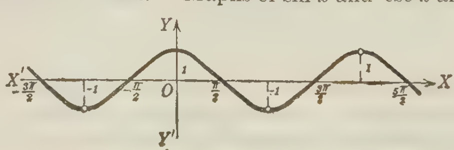

FIG. 130.—Graph of $y = \cos x$.

Figs. 130 and 133, respectively, by drawing the Y-axis through the point $x = -\pi/2$.

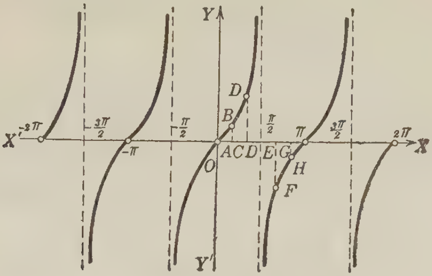

FIG. 131.—Graph of $y = \tan x$.

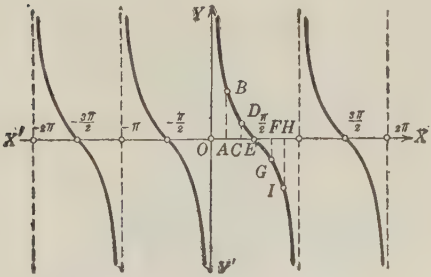

FIG. 132.—Graph of $y = \cot x$.

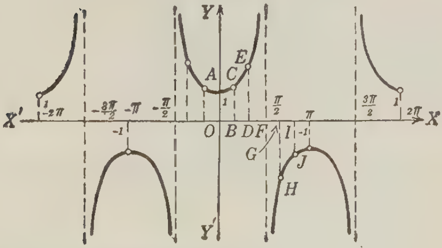

FIG. 133.—Graph of $y = \sec x$.

41. Formulas in plane trigonometry

Relations between functions of the same angle, any quadrant. See Art. 31.

Functions of multiple angles. Sin $2A = 2 \sin A \cos A$. Cos $2A = \cos^2 A - \sin^2 A = 1 - 2 \sin^2 A = 2 \cos^2 A - 1$. Tan $2A = 2 \tan A/(1 - \tan^2 A)$. Cot $2A = (\cot^2 A - 1)/2 \cot A$.

Sin $3A = 3 \sin A - 4 \sin^3 A$. Cos $3A = 4 \cos^3 A - 3 \cos A$. Tan $3A = (3 \tan A - \tan^3 A)/(1 - 3 \tan^2 A)$.

Sin $4A = 4 \sin A \cos A - 8 \sin^3 A \cos A$. Cos $4A = 8 \cos^4 A - 8 \cos^2 A + 1$.

Sin $nA = \sin (n-1) A \cos A + \cos (n-1) A \sin A$. Cos $nA = \cos (n-1) A \cos A - \sin (n-1) A \sin A$.

*Sin $nA = n \cos^{n-1} A \sin A - \binom{n}{3} \cos^{n-3} A \sin^3 A + \binom{n}{5} \cos^{n-5} A \sin^5 A -$, etc.

*Cos $nA = \cos^n A - \binom{n}{2} \cos^{n-2} A \sin^2 A + \binom{n}{4} \cos^{n-4} A \sin^4 A -$, etc.

* In these formulas $\binom{n}{2}$, $\binom{n}{3}$, etc., are binomial coefficients. See Art. 18.

Functions of half angles. Sin $\frac{1}{2}A = \sqrt{\frac{1}{2}(1 - \cos A)}$. Cos $\frac{1}{2}A = \sqrt{\frac{1}{2}(1 + \cos A)}$.

Tan $\frac{1}{2}A = \sqrt{1 - \cos A}/\sqrt{1 + \cos A} = \sin A/(1 + \cos A) = (1 - \cos A)/\sin A$.

Powers in terms of multiple angles. Sin$^2 A = \frac{1}{2}(1 - \cos 2A)$. Cos$^2 A = \frac{1}{2}(1 + \cos 2A)$.

Sin$^3 A = \frac{1}{4}(3 \sin A - \sin 3A)$. Cos$^3 A = \frac{1}{4}(\cos 3A + 3 \cos A)$.

Functions of sum or difference of two angles. Sin $(A + B) = \sin A \cos B + \cos A \sin B$. Sin $(A - B) = \sin A \cos B - \cos A \sin B$.

Cos $(A + B) = \cos A \cos B - \sin A \sin B$.

Cos $(A - B) = \cos A \cos B + \sin A \sin B$.

Tan $(A + B) = (\tan A + \tan B)/(1 - \tan A \tan B)$. Tan $(A - B) = (\tan A - \tan B)/(1 + \tan A \tan B)$.

Cot $(A + B) = (\cot A \cot B - 1)/(\cot A + \cot B)$.

Cot $(A - B) = (\cot A \cot B + 1)/(\cot B - \cot A)$.

Sums, differences, and products of functions.

Sin $A + \sin B = 2 \sin \frac{1}{2}(A + B) \cos \frac{1}{2}(A - B$.

Sin $A - \sin B = 2 \cos \frac{1}{2}(A + B) \sin \frac{1}{2}(A - B)$.

Cos $A + \cos B = 2 \cos \frac{1}{2}(A + B) \cos \frac{1}{2}(A - B)$.

Cos $A - \cos B = -2 \sin \frac{1}{2}(A + B) \sin \frac{1}{2}(A - B)$.

Tan $A + \tan B = \sin (A + B)/\cos A \cos B$.

Tan $A - \tan B = \sin (A - B)/\cos A \cos B$.

Sin$^2 A - \sin^2 B = \sin (A + B) \sin (A - B)$.

Cos$^2 A - \cos^2 B = \cos (A + B) \sin (A - B)$.

Cos$^2 A - \sin^2 B = \cos (A + B) \cos (A - B)$.

Sin $A \sin B = \frac{1}{2} \cos (A - B) - \frac{1}{2} \cos (A + B)$.

Sin $A \cos B = \frac{1}{2} \sin (A + B) + \frac{1}{2} \sin (A - B)$.

Cos $A \cos B = \frac{1}{2} \cos (A + B) + \frac{1}{2} \cos (A - B)$.

Series. (See also Art. 62.)

Sin $x = x - \frac{1}{3!}x^3 + \frac{1}{5!}x^5 - \ldots$ for all values of x in radians.

Cos $x = 1 - \frac{1}{2!}x^2 + \frac{1}{4!}x^4 - \ldots$ for all values of x in radians.

Tan $x = x + \frac{1}{3}x^3 + \frac{2}{15}x^5 + \frac{17}{315}x^7 + \cdot - \ldots$ for values of x in radians numerically less than $\frac{1}{2}\pi$.

Trigonometric functions and exponentials. (See Art. 21.)

Sin $x = \dfrac{e^{ix} - e^{-ix}}{2i}$. Cos $x = \dfrac{e^{ix} + e^{-ix}}{2}$. Tan $x = \dfrac{e^{ix} - e^{-ix}}{e^{ix} + e^{-ix}}$.

$$(\text{Cos } x + i \sin x)^n = \cos nx + i \sin nx.$$

42. Inverse functions

The equation $\sin 30° = \frac{1}{2}$ is also written $30° = \sin^{-1} \frac{1}{2}$. The expression $\sin^{-1} \frac{1}{2}$ is called INVERSE SINE of $\frac{1}{2}$, or "angle whose sine is $\frac{1}{2}$." Similarly $\cos^{-1} a$, $\tan^{-1} a$, $\sec^{-1} a$, $\csc^{-1} a$, $\cot^{-1} a$, are inverse functions, *e.g.*, inverse cosine of a, or angle whose cosine equals a, etc.

Relations between inverse functions. $\text{Sin}^{-1} a = \cos^{-1}\sqrt{1 - a^2} = \tan^{-1} a/\sqrt{1 - a^2} = \cot^{-1}\sqrt{1 - a^2}/a = \sec^{-1} 1/\sqrt{1 - a^2} = \csc^{-1} 1/a$.

$\text{Tan}^{-1} a = \sin^{-1} a/\sqrt{1 + a^2} = \cot^{-1} 1/a = \cos^{-1} 1/\sqrt{1+a^2} = \sec^{-1}\sqrt{1+a^2} = \csc^{-1}\sqrt{1 + a^2}/a$.

$\text{Cos}^{-1} a = \sin^{-1}\sqrt{1 - a^2} = \tan^{-1}\sqrt{1 - a^2}/a = \cot^{-1} a/\sqrt{1 - a^2} = \sec^{-1} 1/a = \csc^{-1} 1\sqrt{1 - a^2}$.

$\text{Sin}^{-1} a \pm \sin^{-1} b = \sin^{-1} (a\sqrt{1 - b^2} \pm b\sqrt{1 - a^2})$.

$\text{Cos}^{-1} a \pm \cos^{-1} b = \cos^{-1} (ab \pm \sqrt{(1 - a^2)(1 - b^2)})$.

$\text{Tan}^{-1} a \pm \tan^{-1} b = \tan^{-1} [(a \pm b)/(1 \mp ab)]$.

43. Spherical trigonometry

Right spherical triangles have six parts, namely, the sides a, b, c, and the angles A, B, C ($= 90°$). (Fig. 134.) Each part is less than 180°. When two of the parts a, b, c, A, B, are given, assuming certain conditions are met (see below), the triangle can be solved, *i.e.*, the unknown parts can be determined. The necessary conditions are: $A + B > 90°$ (since the sum of the three angles must be greater than 180° (Art. 28); an angle and opposite side are either both greater than 90°, both equal to 90°, or both less than 90°.

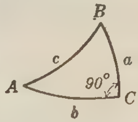

FIG. 134.

Formulas for solving right spherical triangles. $\text{Cos } c = \cos a \cos b$. $\text{Sin } b = \tan a \cot A$. $\text{Sin } a = \tan b \cot B$. $\text{Sin } a = \sin c \sin A$. $\text{Cos } B = \tan a \cot c$. $\text{Cos } A = \cos a \sin B$. $\text{Cos } c = \cot A \cot B$. $\text{Sin } b = \sin c \sin B$. $\text{Cos } B = \cos b \sin A$. $\text{Cos } A = \tan b \cot c$.

In applying the formulas careful attention must be paid to the algebraic signs of the given parts. When an angle and its opposite side are given, there are two solutions.

Example. Solve the right spherical triangle given $B = 33° 50'$, $a = 108°$.

Solution. The formulas in the above group containing both B and a are:

$$\sin a = \tan b \cot B, \qquad \cos B = \tan a \cot c, \qquad \cos A = \cos a \sin B.$$

Solving the first two of these for the unknown part, the results are (1) $\tan b = \sin a \tan B$, (2) $\cot c = \cot a \cos B$. From (1) since $\sin a$ and $\tan B$ are positive, $\tan b$ is positive and b lies between 0° and 90°. By logarithms, $b = 32° 31'$. In (2), $\cot a$ is negative (Art. 32), hence $\cot c$ is negative and c lies between 90° and 180°. In solving (2) by logarithms proceed without regard to algebraic sign of $\cot a$, and find the angle less than 90° whose cot equals $\cot a \cos B$ numerically. This angle is found to be $74° 54'$. Hence $c = 180° - 74° 54' = 105° 6'$. Finally in finding A from $\cos A = \cos a \sin B$, since $\cos a$ is negative, proceed as in determining c. Answer for A is found to be $99° 54'$.

ANALYTIC GEOMETRY

44. Formulas using co-ordinates

Definitions. The RECTANGULAR CO-ORDINATES of a point P in a plane are the distances of the point from two perpendicular lines XX', YY', called AXES OF CO-ORDINATES. (Fig. 135. See also Art. 11.) The distance from YY'

is the ABSCISSA of the point, and is POSITIVE when P is to right of YY', negative when to left. The distance from XX' is the ORDINATE of the point, POSITIVE when P is above XX', NEGATIVE when below. The axes divide the plane into four QUADRANTS. Signs of co-ordinates for points in various quadrants are indicated in Fig. 136. Co-ordinates a and b of point P are written $P(a, b)$, the first number being the abscissa. The intersection O of the axes is called the ORIGIN. The abscissa of any point on YY' (Y-axis) is zero and the ordinate of any point on XX' (X-axis) is zero. Co-ordinates of the origin are (0, 0) (**12**). OBLIQUE CO-ORDINATES are sometimes used, the axes forming an angle A not equal to 90°. The co-ordinates of a point are the lengths of lines drawn from the point to the axes parallel to respective axes. POLAR CO-ORDINATES, see Art. 48.

Length l of line joining two points (x_1, y_1) **and** (x_2, y_2) **is**

$$l = \sqrt{(x_1 - x_2)^2 + (y_1 - y_2)^2}.$$

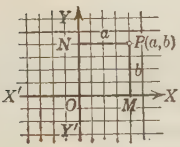

FIG. 135.

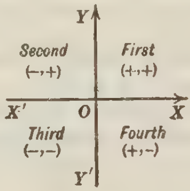

FIG. 136.

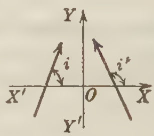

FIG. 137.

Slope of a line, produced if necessary to meet X-axis, is the tangent of the angle measured from the X-axis around to the line in a counterclockwise direction. The angle is called the INCLINATION. In Fig. 137, the inclination is marked, i, i' for the respective lines. Slope is denoted by letters m, m', etc. Thus $m = \tan i$, $m' = \tan i'$, etc. The slope may have any value, positive or negative. Parallel lines have equal slopes. For two perpendicular lines, the slope of one is the negative reciprocal of the slope of the other. If (x_1, y_1) and (x_2, y_2) are points on a line, the slope is

$$m = (y_1 - y_2)/(x_1 - x_2).$$

Lines parallel to OX have slope zero, those parallel to OY have slope equal to infinity. ($\tan 0° = 0$, $\tan 90° = \infty$, Art. 38.)

Point of division. If $P_1(x_1, y_1)$, $P_2(x_2, y_2)$, $P(x, y)$ are three points on a line, then $x = (x_1 + rx_2)/(1 + r)$ and $y = (y_1 + ry_2/(1 + r)$, where r is numerically equal to the ratio of lengths P_1P and PP_2; r is positive when P is on segment P_1P_2, negative when outside.

Mid-point. Co-ordinates (x, y) of mid-point ($r = 1$) are $= \frac{1}{2}(x_1 + x_2)$, $\frac{1}{2}(y_1 + y_2)$.

Area of triangle with vertices (x_1, y_1), (x_2, y_2), (x_3, y_3) is $\frac{1}{2}(x_1y_2 - x_2y_1 + x_2y_3 - x_3y_2 + x_3y_1 - x_1y_3)$.

This may be written by determinants (Art. 14). The formula gives an area with a negative sign when the order of vertices on the perimeter is clockwise.

$$\frac{1}{2}\begin{vmatrix} x_1 & y_1 & 1 \\ x_2 & y_2 & 1 \\ x_3 & y_3 & 1 \end{vmatrix}$$

A convenient way to find the area in any given numerical case is the following: Write abscissas and ordinates in rows as indicated, repeating the first abscissa and ordinate. (1) Multiply each abscissa by the ordinate in the next column, and add the results. (2) Multiply each ordinate by the abscissa in next column and add results. (3) Subtract the last sum from the first sum and divide by 2.

$$\begin{matrix} x_1 & x_2 & x_3 & x_1 \\ y_1 & y_2 & y_3 & y_1 \end{matrix}$$

Area of a polygon with vertices given may be found in the same manner by writing down the co-ordinates of successive points on the perimeter as in the annexed scheme and following the rule as just given.

$$\begin{matrix} x_1x_2 \ . \ . \ . \ x_nx_1 \\ y_1y_2 \ . \ . \ . \ x_nx_1 \end{matrix}$$

45. Curve and equation

Locus of an equation in two variables (usually x and y) representing rectangular co-ordinates is a curve (or group of curves) passing through all points whose co-ordinates satisfy that equation, and through such points only. To PLOT the locus of a given equation, solve the equation for one variable in terms of the other variable, assume values for the latter, compute corresponding values of the first variable, plot the points with co-ordinates thus determined, and draw a smooth curve through these points.

Example. (Fig. 138.) Plot locus of

$$x^2 + y^2 + 6x - 16 = 0.$$

Solving for y,

$$y = \pm\sqrt{16 - 6x - x^2}.$$

Compute y for assumed values of x as shown in the adjacent table.

x	y	x	y
0	± 4	0	± 4
1	± 3	-1	± 4.6
2	0	-2	± 4.9
3	imag.	-3	± 5
4	"	-4	± 4.9
5	"	-5	± 4.6
6	"	-6	± 4
7	"	-7	± 3
		-8	0
		-9	imag.

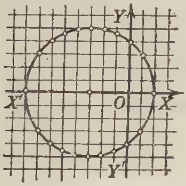

FIG. 138.

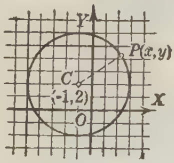

FIG. 139.

Symmetry of a curve with respect to the axes or origin should be noticed, and may be determined by the following tests: Curve is symmetric with respect to the X-axis, or to the Y-axis, or to the origin, when the given equality is unaffected by replacing y by $-y$, or x by $-x$, or x and y simultaneously by $-x$ and $-y$, respectively.

In the example given, the circle is symmetric with respect to the X-axis.

Equation of a curve (or locus of a point satisfying a given condition) is that equation in two variables (usually x and y) representing co-ordinates such that the co-ordinates of every point on the curve will satisfy the equation, and conversely, every point whose co-ordinates satisfy the equation will lie on the curve.

Example. Find the equation of the circle whose center is $C(-1, 2)$ and radius 4.
Let $P(x, y)$ be any point on the circle. (Fig. 139.) Then $PC = 4$ by definition of circle. But PC = length of line joining (x, y) and $(-1, 2) = \sqrt{(x + 1)^2 + (y - 2)^2}$ (Art. 44). Substitute this expression in $PC = 4$, square both sides, transpose and reduce. Result is $x^2 + y^2 + 2x - 4y - 11 = 0$, the required equation of the circle.

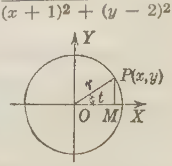

FIG. 140.

Points of intersection of two curves (loci) whose equations are given are those points whose co-ordinates satisfy both equation. These co-ordinates are found by solving the given equations. See Art. 9, 10.

Parametric equations of a curve arise when the co-ordinates x and y of a point on the curve are each expressed in terms of a third variable (called PARAMETER).

Example. In the circle of Fig. 140, if $OP = r$, angle $MOP = t$, then $x = OM = r \cos t$, and $y = MP = r \sin t$, are parametric equations of the circle. Squaring and adding gives the rectangular equation $x^2 + y^2 = r^2$.

Elimination of parameter gives the rectangular equation. Parametric equations for a curve may be found in an infinite variety of ways. When a point describes a curve in a given manner, the parametric equations may often be found directly, and rectangular equations from these, if desired. See Art. 54.

46. Straight lines

Notation (Fig. 141). OA = intercept on X-axis $= a$. OB = intercept on Y-axis $= b$. ON = perpendicular distance from origin $= p$. Slope $m = \tan i$ (Art. 44). The angle that ON forms with OX, measured counter-clockwise, $= n$.

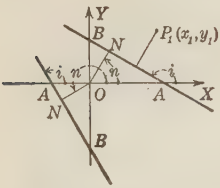

FIG. 141.

Equations of straight lines. Let $P(x, y)$ be any point on the line.

$y = mx + b$, given m and b.

$x/a + y/b = 1$, given a and b.

$y - y_1 = m(x - x_1)$, given one point (x_1, y_1) and m.

$(y - y_1)/(x - x_1) = (y_1 - y_2)/(x_1 - x_2)$, given two points (x_1, y_1), (x_2, y_2).

$x \cos n + y \sin n = p$, given p and n.

Line parallel to X-axis; $y = b$; parallel to Y-axis, $x = a$. Equation of X-axis, $y = 0$; of Y-axis, $x = 0$.

Polar equation. Art. 48.

General equation of first degree in x, y, is $Ax + By + C = 0$. The locus is a straight line. $m = \tan i = -A/B$; $a = -C/A$; $b = -C/B$; $p = \pm C/\sqrt{A^2 + B^2}$, $n = \sin^{-1} B/\sqrt{A^2 + B^2} = \cos^{-1} A/\sqrt{A^2 + B^2}$. Choose the sign of the radical opposite to the sign of C.

Perpendicular distance d **from line** $Ax + By + C = 0$ **to point** $P_1(x_1, y_1)$. $d = (Ax_1) + By_1 + C)/\sqrt{A^2 + B^2}$.

If $C \neq 0$, and the radical is given the sign opposite to C, d is positive when P_1 and O are on opposite sides of the line, negative when on the same side.

Relations between two lines $A_1x + B_1y + C_1 = 0$ and $A_2x + B_2y + C_2 = 0$. The lines are parallel if $A_1B_2 - A_2B_1 = 0$; they are perpendicular if $A_1A_2 + B_1B_2 = 0$. The angle between the lines $= \tan^{-1} (A_1B_2 - A_2B_1)/(A_1A_2 + B_1B_2)$.

Locus of an equation of higher degree in x **and** y is a group of straight lines when the equation can be written as the product of real factors of the first degree equal to zero. The locus consists of the lines obtained by setting the factors equal to zero.

Example. Equation $9x^2 - y^2 = 0$ may be written $(3x - y)(3x + y) = 0$. Locus is pair of intersecting lines $3x - y = 0$, $3x + y = 0$.

47. Circles

Notation. Center $C\ (a, b)$; radius $= r$; $P(x, y)$ = any point on the circumference.

Equations of circles.

$(x - a)^2 + (y - b)^2 = r^2$, given radius r and center (a, b).
$x^2 + y^2 - 2ax = 0$, center (a, o) on X-axis; passes through origin.
$x^2 + y^2 - 2by = o$, center (o, b) on Y-axis; passes through origin.
$x^2 + y^2 = r^2$, center at origin.

Polar equation. Art. 48.

Locus of $x^2 + y^2 + Dx + Ey + F = 0$ is a circle when $D^2 + E^2 - 4F$ is positive. Center is $(-\frac{1}{2}D, -\frac{1}{2}E)$, radius $= \frac{1}{2}\sqrt{D^2 + E^2 - 4F}$. The locus is a POINT CIRCLE when $r = o$. The equation has no locus when $D^2 + E^2 - 4F < 0$.

48. Polar co-ordinates

Polar co-ordinates of a point P in a plane (Fig. 142) are its distance OP from a fixed point O (the POLE) and the angle AOP between OP and a fixed line OA (POLAR AXIS). Distance OP is called the RADIUS VECTOR of P, angle AOP is called the VECTORIAL ANGLE. The latter is positive or negative as

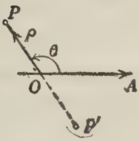

FIG. 142.

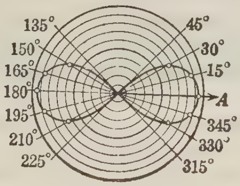

FIG. 143.

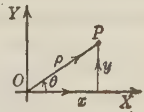

FIG. 144.

in Trigonometry (Art. 35). The radius vector is positive when P lies on the terminal side of the vectorial angle, negative when on the terminal side produced through the pole. Polar co-ordinates are denoted by Greek letters ρ (*rho*) and θ (*theta*) for polar distance and vectorial angle, respectively. Equations in polar co-ordinates ρ and θ (POLAR EQUATIONS) are plotted by calculating corresponding values of ρ and θ, plotting the points, and drawing a smooth curve through them.

Example. Figure 143 shows the locus of

$$\rho^2 = a^2 \cos 2\theta.$$

The adjoining table gives corresponding values of ρ and θ.

$\rho^2 = a^2 \cos 2\theta$			
θ	2θ	$\cos 2\theta$	ρ
0	0	1	$\pm a$
15°	30°	.866	$\pm .93a$
30°	60°	.500	$\pm .7a$
45°	90°	0	0

Length l of line joining (ρ_1, θ_1) and $\rho_2, \theta_2)$ is

$$l = \sqrt{\rho_1^2 + \rho_2^2 - 2\rho_1\rho_2 \cos (\theta_1 - \theta_2)}.$$

Relations between rectangular and polar co-ordinates of a point P. (Fig. 144.) $x = \rho \cos \theta$, $y = \rho \sin \theta$. $\rho = \pm\sqrt{x^2 + y^2}$. $\theta = \tan^{-1} y/x$.

Polar equations for a straight line and a circle. $P(\rho,\theta)$ any point on line, or circumference.

Straight line

$\rho = p \cos (\theta - n)$, given n and p. (Art. 46.)
Locus of $\rho(A \cos \theta + B \sin \theta) + C = 0$ is a straight line.
Equation of a line through pole: $\theta = a$ *constant.*

Circle

$\rho = 2r \cos \theta$; center on polar axis, radius r, circle passes through the pole.
$\rho = 2r \sin \theta$; center $(r, 90°)$, radius r, circle passes through pole.
$\rho = r$, center at pole.
Locus of $\rho^2 + \rho (D \cos \theta + E \sin \theta) + F = 0$ is a circle. (See Art. 47.)

49. Parabola

Definitions. A PARABOLA is a curve described by a point moving so that it remains always equidistant from a fixed point (FOCUS) and a fixed line (DIRECTRIX). NOTATION. (Figs. 145, 146.) Focus F, directrix DD', distance from focus to directrix $= p$. The line drawn through the focus perpendicular to the directrix is the AXIS of the curve. The curve is symmetric with respect to its axis. The point on the axis midway between focus and directrix is the VERTEX. The vertex lies on the parabola. The chord drawn through the focus parallel to the directrix is the LATUS RECTUM; length $= 2p$.

Equations of parabola

$y^2 = 2px$; vertex at origin, axis of curve along X-axis, focus $(\frac{1}{2}p, 0)$, equation of directrix $x = -\frac{1}{2}p$. $P(x, y)$ any point on curve. (Fig. 145.)

$x^2 = 2py$; vertex at origin, axis of curve along Y-axis, focus $(0, \frac{1}{2}p)$, equation of directrix, $y = -\frac{1}{2}p$. (Fig. 146.)

$(y - b)^2 = 2p(x - a)$; vertex (a, b), axis of curve parallel to X-axis.

$(x - a)^2 = 2p(y - b)$; vertex (a, b) axis of curve parallel to Y-axis.

Polar equation. $\rho = p/(1 - \cos \theta)$; pole at focus, polar axis along axis of curve.

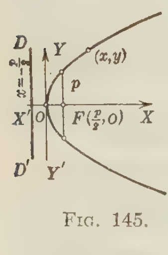

FIG. 145.

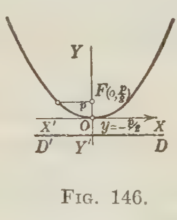

FIG. 146.

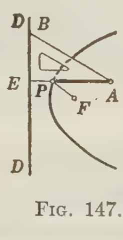

FIG. 147.

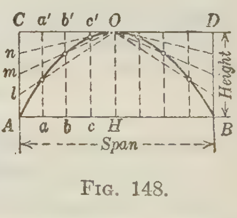

FIG. 148.

Locus of $x^2 + Dx + Ey + F = 0$, E **not zero, is a parabola with vertex**

$$(-\tfrac{1}{2}D, (D^2 - 4F)/4E),$$

axis parallel to Y-axis, latus rectum $= -E$.

Locus of $y^2 + Dx + Ey + F = 0$, D **not zero, is a parabola with vertex**

$$((E^2 - 4F)/4D, -\tfrac{1}{2}E),$$

axis parallel to X-axis, latus rectum $= -D$.

Parabola with axis not parallel to XX' or YY', see Art. 53.

Construction of parabola. Given focus F and directrix DD'. (Fig. 149.) Draw axis MX. Bisect FM, giving vertex V. Through any point A to right of V draw AB parallel to DD'. From F as center with a radius equal to MA strike arcs to intersect AB at P and Q. Then P and Q are points on the curve. Any number of points may be constructed in this manner. Figure 147 shows how to trace a parabola by sliding a triangle ABE along DD. Ends of string of length AE are fastened at A and F.

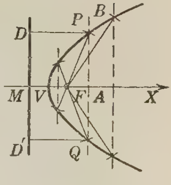

FIG. 149.

To construct a parabolic arch with given span ($2a$) and height (h). (Fig. 148.) Draw rectangle $ABCD$, divide AC, AH, OC into the same number of equal parts, draw lines aa', bb', cc', On, Om, and Ol. The intersections are points on the arch. With OH as Y-axis, CD as X-axis, the equation of the parabola in Fig. 148 is $x^2 = a^2y/h$.

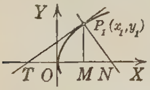

FIG. 150.

Tangent and normal (Fig. 150).

$y_1y = p(x + x_1)$ is the equation of the tangent to $y^2 = 2px$ at $P_1(x_1, y_1)$.

$y_1(x-x_1) + p(y-y_1) = 0$ is the equation of the normal P_1N. SUBTANGENT ($=MT$) is bisected at the vertex ($TO = OM$). SUBNORMAL ($=MN$) is of constant length $= p$.

To construct a tangent at a given point P_1 (Fig. 150), draw P_1M through P_1 perpendicular to the axis OX, lay off $OT = OM$, draw TP_1, which is the tangent required. Line $y = mx + c$ is a tangent to $y^2 = 2px$ when $c = p/2m$. Two perpendicular tangents intersect on the directrix and the line joining the points of contact passes through the focus. The foot of the perpendicular drawn from the focus upon a tangent lies on the tangent drawn at the vertex. The tangent and normal bisect the angles formed by lines drawn through the point of contact and the focus and through the point of contact parallel to the axis. (Fig. 151.) Two parabolas with common focus and axis (CONFOCAL PARABOLAS) and vertices upon opposite sides of the focus intersect at right angles. The equation $y^2 = 2px + p^2$ represents a system of confocal parabolas, p having any constant value. The equation of a parabola referred to the tangents drawn at the extremities of the latus rectum as axes is $\sqrt{x} + \sqrt{y} = \sqrt{a}$, where $a = p\sqrt{2}$. (Fig. 152).

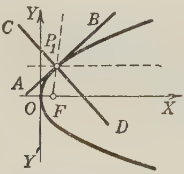

FIG. 151.

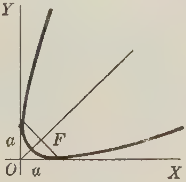

FIG. 152.

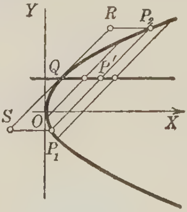

FIG. 153.

A diameter is a line drawn parallel to the axis of a parabola (Fig. 153). The diameter bisects all chords parallel to the tangent at the point where the diameter meets the parabola. The distance of a diameter from the axis $=p/m$ where m = the slope of the chords. The area of the parabolic segment P_1QP_2, cut off by any chord P_1P_2, = ⅔ area of parallelogram P_1P_2RS. (Fig. 153.)

50. Ellipse

Definitions. An ellipse is a curve described by a point moving so that the sum of its distances from two fixed points (FOCI) remains constant. NOTATION. (Figs. 154, 155.) Foci F, F'. $PF + PF' = 2a$. $FF' = 2c$. AA' = MAJOR AXIS $= 2a$. BB' = MINOR AXIS $= 2b$. $a > b$. VERTICES A, A' are the extremities of the major axis. CENTER, O. LATUS RECTUM is the chord drawn

through the focus perpendicular to the major axis, length $= 2b^2/a$. ECCENTRICITY, $e = c/a$. $e < 1$. Lines DD, $D'D'$, (Fig. 156) drawn parallel to the minor axis, at distances $\pm a^2/c$ from the center, are DIRECTRICES. $PF = e \times PE$, $PF' = e \times PE'$. An ellipse is also a curve described by a point moving so that the ratio of its distances from a fixed point (focus) and fixed line (directrix) remains constant (eccentricity) and less than unity.

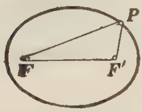

FIG. 154.

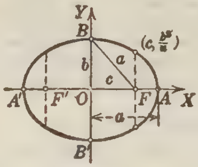

FIG. 155.

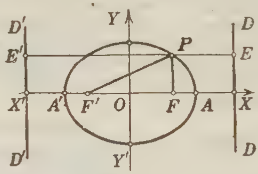

FIG. 156.

Formulas. $a^2 = b^2 + c^2$. $c = ae$. $b^2 = a^2(1 - e^2)$. $e = \sqrt{1 - b^2/a^2}$.

Equations of ellipse.

$x^2/a^2 + y^2/b^2 = 1$ or $y = \pm b\sqrt{a^2 - x^2}/a$; center (0, 0), foci on X-axis, $P(x, y)$ any point on curve.

$(x - h)^2/a^2 + (y - k)^2/b^2 = 1$, center (h, k), major axis parallel to X-axis.

Interchange a and b in the two preceding equations if the major axis is vertical.

Parametric equations. $x = a \cos \phi$, $y = b \sin \phi$, where $\phi =$ ECCENTRIC ANGLE of point $P(x, y)$, $(= \angle XOM$, Fig. 156).

Focal radii of P (x, y, Fig. 156). $F'P = a + ex$, $FP = a - ex$.

Polar equation. $\rho = a(1 - e^2)/(1 - e \cos \theta)$; pole at left-hand focus, polar axis drawn through other focus. (Fig. 156.) $F'P = \rho$, $\angle OF'P = \theta$.

Locus of $Ax^2 + By^2 + Dx + Ey + F = 0$, A and B positive numbers (not zero), is an ellipse when $R = \frac{1}{4}(D^2/A + E^2/B - 4F) > 0$. Center is $(-D/2A, -E/2B)$; semi-axes $(\sqrt{R/A}, \sqrt{R/B})$ major-axis is parallel to X-axis or Y-axis according as $A < B$, or $A > B$. For $A = B$, locus is a circle. For $R = 0$, locus reduces to point $(-D/2A, -E/2A)$, a POINT-ELLIPSE. The equation has no locus when $R < 0$.

For an ellipse with major axis oblique to the X-axis, see Art. 53.

Construction of ellipse. When the major and minor axes AA', BB' are given, draw circles upon those lines as diameters (Fig. 157) and from any point M on the larger circle draw radius OM, and draw SP and MR parallel to OA and OB, respectively, to intersect at P, on the ellipse. An ellipse is a flattened circle, in the sense that the ordinates of the large circle in Fig. 157 are reduced in the ratio $b : a$ to the given ordinates of the ellipse. Fig. 158 shows an instrument for drawing ellipses. A, B are adjustable nuts on the crossbar PAB. These slide in perpendicular grooves XX', YY'. When the crossbar is moved, P traces an ellipse with semi-axes AP, BP.

For other constructions, Art. 54.

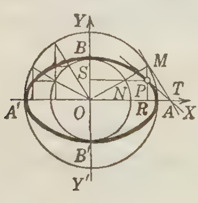

FIG. 157.

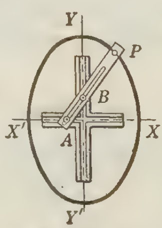

FIG. 158.

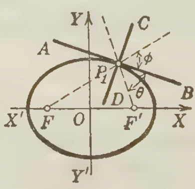

FIG. 159.

Tangent and normal to ellipse $b^2x^2 + a^2y^2 = a^2b^2$.
$b^2x_1x + a^2y_1y = a^2b^2$ is the equation of the tangent at (x_1, y_1).
$a^2y_1x - b^2x_1y = (a^2 - b^2)x_1y_1$ is the equation of the normal through (x_1y_1).
$y = mx + c$ is a tangent when $c = \pm\sqrt{a^2m^2 + b^2}$.

To construct a tangent at P, Fig. 157, extend ordinate RP to meet the outer circle at M and draw tangent MT; then TP is tangent to the ellipse. Two perpendicular tangents intersect on the circle $x^2 + y^2 = a^2 + b^2$ (DIRECTOR CIRCLE). The foot of the perpendicular from the focus to a tangent lies on the circle $x^2 + y^2 = a^2$. The tangent and normal bisect angles formed by focal radii through the point of contact (Fig. 159).

To draw tangents from an external point P (Fig. 160). Draw secants PQR, PST; chords QT, RS, intersecting at L, and secants QS, RT, intersecting at M. Then LM intersects the ellipse in points of contact A, B.

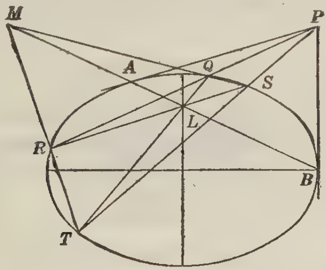

FIG. 160.

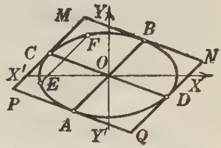

FIG. 161.

Diameter is a line drawn through the center. Tangents drawn at the extremities of a diameter are parallel. All chords parallel to these tangents are bisected by the diameter. In Fig. 161, AB and CD are CONJUGATE DIAMETERS, each being parallel to chords bisected by the other. If m, m' are slopes of the conjugate diameters, $mm' = -b^2/a^2$. The area of the circumscribed parallelogram $MNQP$ formed by tangents drawn at the extremities of conjugate diameters equals $4ab$. If $2a'$, $2b'$, are the lengths of AB, CD, then $a'^2 + b'^2 = a^2 + b^2$.

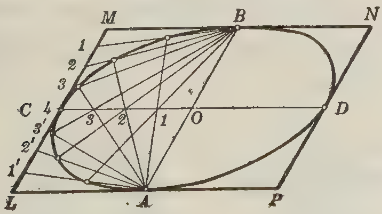

FIG. 162.

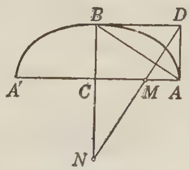

FIG. 163.

To construct an ellipse, given a pair of conjugate diameters AB, CD (Fig. 162). Draw the parallelogram $LMNP$, divide MC and OC into the same number of equal parts, draw lines from B and A, through like-numbered points. These lines intersect on the ellipse.

Radii of curvature (Art. 61) for points A, B, at extremities of the axes are determined (Fig. 163) by drawing a line from vertex D of the rectangle $ADBC$ perpendicular to the chord AB. Then M, N are centers of curvature for A, B, respectively, and AM, BN, are radii of curvature. $AM = b^2/a$, $BN = a^2/b$.

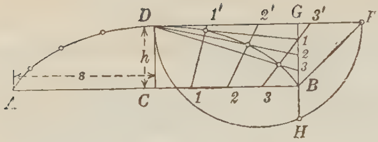

FIG. 164.

To construct an elliptic arch of given height (h) **and span** ($2s$) **with axes in a given ratio** (m). (Fig. 164) $GH = mh$, DF is diameter of the circle drawn through H. Lines BG, BC, DF are divided into the same number of equal parts and lines drawn to intersect on the ellipse as shown. Axes are $h + s^2/m^2h$ (along CD produced), and $mh + s^2/mh$.

Approximate construction of ellipse by circular arcs.

With four centers (Fig. 165)

Lay off $CF = OB - OC$, bisect BF at S, and draw SH perpendicular to BC. Set off $OG' = OG$, and $OH' = OH$. Then the four centers are G, H, G', H', and the radii are GB, HC, $G'A$, $H'D$.

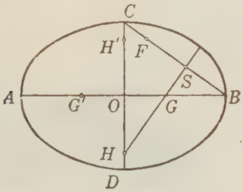

FIG. 165.

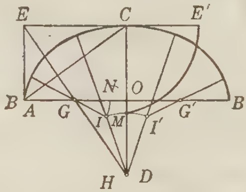

FIG. 166.

With eight centers (Fig. 166)

$OB = a$, $OC = b$. Draw EGH perpendicular to AC. Then G, H are centers with radii GA, HC (radii of curvature at A and C). Produce EC to E' making $CE' = OC$. Upon EE' as a diameter draw a circle cutting CD at M. Then $CM = \sqrt{ab}$, and is the third radius. (See Fig. 55.) Lay off $AN = CM$, and from G, H strike arcs with radii GN, HM, intersecting at I, the third center for the elliptic arc from A to C. Eight centers are necessary to complete the ellipse. Radius $AG = b^2/a$, $HC = a^2/b$, and the third radius CM is the mean proportional between AG and HC.

51. Hyperbola

Definitions. A hyperbola is a curve traced by a point moving so that the difference of its distances from two fixed points (FOCI) remains constant. NOTATION. Figs. 167, 168. Foci F, F'. $FF' = 2c$. $PF' - PF = 2a$. AA' = TRANSVERSE AXIS $= 2a$. BB' = CONJUGATE AXIS $= 2b$. VERTICES are A, A'.

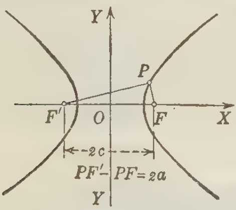

FIG. 167.

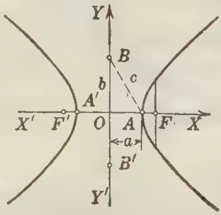

FIG. 168.

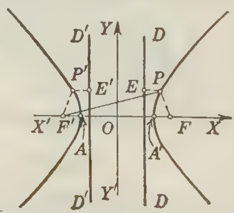

FIG. 169.

CENTER, is O. LATUS RECTUM is a chord drawn through the focus perpendicular to the transverse axis produced; length $= 2b^2/a$. ECCENTRICITY $e = c/a$ $e > 1$. Lines DD, $D'D'$, (Fig. 169) drawn parallel to the conjugate axis at distances $\pm a^2/c$ from the center are DIRECTRICES. $PF = e \times PE$, $P'F' = e \times P'E'$. The hyperbola is also a curve traced by a point so moving that the

ratio of its distances from a fixed point (focus) and fixed line (directrix) remain constant (eccentricity) and greater than unity.

Formulas. $c^2 = a^2 + b^2$. $c = ae$. $b^2 = a^2(e^2 - 1)$. $e = \sqrt{1 + b^2/a^2}$.

Equations of a hyperbola.

$x^2/a^2 - y^2/b^2 = 1$ or $y = \pm b\sqrt{x^2 - a^2}/a$; center (0, 0); foci on X-axis, $P(x, y)$ any point on curve.

$(x - h)^2/a^2 - (y - k)^2/b^2 = 1$, center (h, k), transverse axis parallel to X-axis.

If the transverse axis is vertical, interchange x and y, and h and k, in the two preceding equations.

Parametric equations. $x = a \cosh u$, $y = b \sinh u$. (For the meaning of u, see Art. 29.)

Focal radii of P are $F'P = ex + a$, $FP = ex - a$. (Fig. 167.)

Polar equation, $\rho = a(e^2 - 1)/(e \cos\theta - 1)$; pole at left-hand focus, polar axis drawn through other focus. (Fig. 167.) $F'P = \rho$, $\angle XF'P = \theta$.

Conjugate hyperbolas have the property that the transverse and conjugate axes of one are respectively the conjugate and transverse axes of the others. Fig. 170. The equations differ only in the sign of the constant term and are $x^2/a^2 - y^2/b^2 = \pm 1$.

Asymptotes of $x^2/a^2 - y^2/b^2 = 1$ are the lines $x/a - y/b = 0$, $x/a + y/b = 0$. Conjugate hyperbolas have the same asymptotes. The diagonals of the rectangle in Fig. 170 lie on the asymptotes. The branches of the hyperbola approach infinitely near its asymptotes as they recede to infinity.

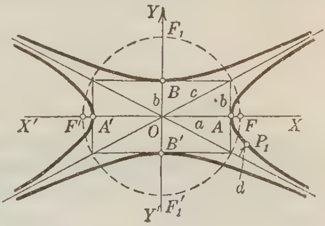

FIG. 170.

Rectangular hyperbola, has equal axes ($a = b$), and asymptotes perpendicular. $e = \sqrt{2}$. The equation is, $x^2 - y^2 = a^2$; foci $(\pm a\sqrt{2}, 0)$. The equation referred to the asymptotes as axes is, $2xy = \pm a^2$. A rectangular hyperbola is also called an EQUILATERAL HYPERBOLA. (See also below.)

Locus of $Ax^2 - By^2 + Dx + Ey + F = 0$, A and B positive numbers (not zero), is a hyperbola when $R = \frac{1}{4}(D^2/A - E^2/B - 4F)$ is not zero. Center is $(-D/2A, E/2B)$; semi-axes $\sqrt{|R/A|}$, $\sqrt{|R/B|}$ (absolute values, see Art. 6); transverse axis is parallel to X-axis or Y-axis according as $R > 0$, or < 0. When $A = B$, the locus is a rectangular hyperbola. If $R = 0$, the locus is a pair of lines intersecting at $(-D/2A, E/2B)$, with slopes $\pm\sqrt{A/B}$.

Locus of $2Cxy + Dx + Ey + F = 0$, C not zero, is a rectangular hyperbola when $R = \frac{1}{4}(DE - CF)/C^2$ is not zero. Center is $(-E/2C, -D/2C)$; $a^2 = |R|$; asymptotes are parallel to OX, OY. When $R = 0$, the locus is a pair of lines $x + E/2C = 0$, $y + D/2C = 0$. See also Art. 53.

Construction of hyperbola. When foci F, F_1, and transverse axis AB are given, points on the curve may be constructed as in Fig. 171. $FR = FJ =$ any radius $> AB$. $JE = AB$. $F_1R = FE = FJ - AB$.

In Fig. 172, focus and directrix are given. Triangle JUV is moved along the ruler edge (directrix), one end of a string of length JV is fastened at J, the other end at F (focus), and kept taut by a pencil point at P. $PF = PV$. Distance from P to the ruler $= PV \sin \angle UVJ = PF \sin \angle UVJ$. Hence eccentricity $= \csc \angle UVJ$.

When asymptotes OX, OY and one point A on the curve are given, construction is shown in Fig. 173 (which is drawn for a rectangular hyperbola): $AN_2 = M_2P_2$; $AN_1 = M_1P_1$, etc.

Tangent and normal to $b^2x^2 - a^2y^2 = a^2b^2$.

$b^2x_1x - a^2y_1y = a^2b^2$, is the equation of the tangent at (x_1, y_1).

$a^2y_1x - b^2x_1y = (a^2 - b^2)x_1y_1$, is the normal through (x_1, y_1).

$y = mx + c$ is a tangent when $c = \pm\sqrt{a^2m^2 - b^2}$.

To construct a tangent at Q (Fig. 171), draw FQ, F_1Q, and construct the bisector of the angle FQF_1. This is the desired tangent. Two perpendicular tangents intersect on the circle $x^2 + y^2 = a^2 - b^2$. (Impossible when $a < b$.) The foot of the perpendicular from the focus upon a tangent lies on circle $x^2 + y^2 = a^2$. Tangent and normal bisect angles formed by the focal radii through the point of contact. The portion of a tangent lying between its intersection with asymptotes is bisected at the point of contact, and forms with the asymptotes a triangle of constant area ab. Hence to draw a tangent at A (Fig. 173) when the asymptotes are given, draw AM, AR, each parallel to an asymptote. Lay off $MT = OM$, $RN = OR$, and draw NT. This is the tangent required.

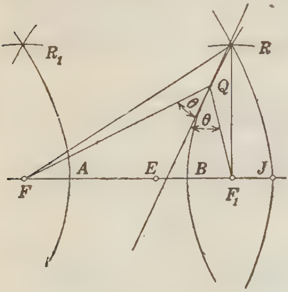

FIG. 171.

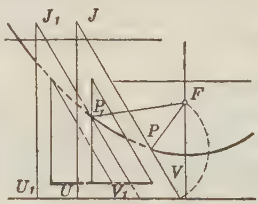

FIG. 172.

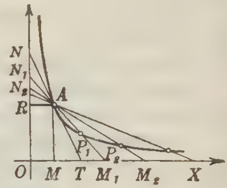

FIG. 173.

Diameter is a line drawn through the center, and will intersect the hyperbola or conjugate hyperbola (asymptotes excluded). The tangents drawn at the extremities of a diameter are parallel. All chords parallel to these tangents terminating in a conjugate hyperbola are bisected by the diameter. In Fig. 174, AB, CD are conjugate diameters, each bisects chords parallel to the other. Product of slopes $= b^2/a^2$. The area of the parallelogram formed by tangents at A, B, C, $D = 4ab$. The vertices are on the asymptotes. $\overline{OB}^2 + \overline{OC}^2 = a^2 + b^2$.

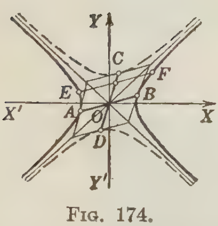

FIG. 174.

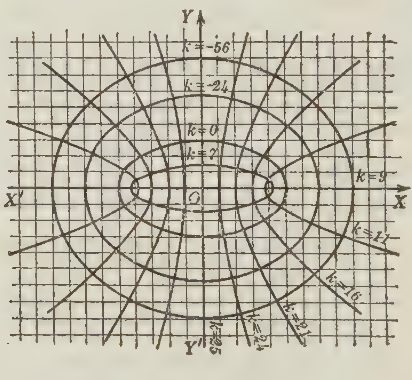

FIG. 175.

Confocal ellipses and hyperbolas. An ellipse and a hyperbola with common foci intersect at right angles. The equation $x^2/(a^2 + k) + y^2(b^2 + k) = 1$, for values of $k > -a^2$, represents a system of curves composed of confocal ellipses and hyperbolas. (Fig. 175. $a = 5$, $b = 3$.)

52. Transformation of rectangular co-ordinates

Notation. New axes of co-ordinates $O'X'$, $O'Y'$, are drawn through a new rigin $O'(h, k)$. Co-ordinates of any point P are (x, y) referred to old axes and $x', y')$ referred to the new axes.

Translation. If the new axes are parallel to the original axes, $x = x' + h$, $y = y' + k$.

Translation and rotation. If the new axis $O'X'$ makes an angle θ with the riginal X-axis, $x = x' \cos\theta - y' \sin\theta + h$, $y = x' \sin\theta + y' \cos\theta + k$.

By these formulas a given equation can be transformed so that the new axes f co-ordinates assume any desired position. By suitable choice of h, k, and θ, eductions of equations to simpler forms may often be effected. (See below.)

53. Locus of $Ax^2 + 2Bxy + Cy^2 + 2Dx + 2Ey + F = O$ (general equation of the second degree)

By rotation of the axes of co-ordinates through the angle $\theta = \frac{1}{2} \tan^{-1} 2B/(A - C)$, the equation will assume a form in which the xy-term is lacking. Hence the locus comes under the cases already discussed.

Tests are given in the following table, excluding the case of no locus.

Test	General case	Exceptional case
$B^2 - AC = 0$	Parabola	Two parallel lines; one line
$B^2 - AC < 0$	Ellipse	Point ellipse
$B^2 - AC > 0$	Hyperbola	Two intersecting lines

A conic section is a curve traced by a point moving so that the ratio (called ECCENTRICITY) of its distance from a fixed point (FOCUS) and a fixed line (DIRECTRIX) is constant. The polar equation, is $\rho = ep/(1 - e\cos\theta)$, pole at focus, polar axis perpendicular to directrix, distance of focus from directrix $= p$, eccentricity $= e$. A conic section is a parabola, ellipse, or hyperbola according as $e = 1$, $e < 1$, or $e > 1$. Plane sections of a right circular conical surface are conic sections, a parabola when the plane is parallel to an element, an ellipse when the plane cuts all elements, a hyperbola in other cases.

54. Locus problems and parametric equations.

It is often easier to express the rectangular co-ordinates x, y of a moving point P in terms of a parameter (parametric equations of the locus of P, Art. 45) than to derive the rectangular equation directly. Study of the problem will determine the choice of parameter.

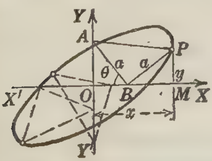

FIG. 176.

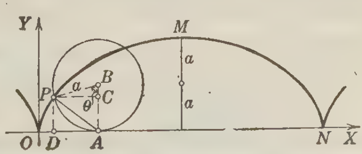

FIG. 177.

Example. A rigid isosceles right-triangular frame moves so that the extremities of one side move on perpendicular lines. Find the curve traced by the third vertex.

Solution. In Fig. 176, choose $\angle ABO = \theta$ for a parameter. The side AB of the triangle $= a$. Then $x = OB + BM = AB \cos\theta + BP \cos(90° - \theta)$, $y = MP = BP \sin(90° - \theta)$. Hence $x = a(\cos\theta + \sin\theta)$, $y = a\cos\theta$. The rectangular equation is $x^2 - 2xy + 2y^2 = a^2$, and the locus is an ellipse. (See Art. 53.)

Cycloid is a curve traced by a point P on the circumference of a circl which rolls without slipping on a straight line. The parametric equation (Fig. 177), are $x = a(\theta - \sin\theta)$, $y = a(1 - \cos\theta)$, θ in radians. The rect angular equation is, $x = a\ \text{vers}^{-1}y/a - \sqrt{2ay - y^2}$.

Construction of cycloid, is shown in Fig. 178, in which $M_1D_1 = CC_1$, $M_2D_2 = CC_2$ $M_3D_3 = CC_3$, etc.

The NORMAL to the cycloid at P passes through A (Fig. 177). A point Q on the radiu BP (Fig. 177), or the radius produced, describes a PROLATE CYCLOID if Q is inside of th rolling circle, and a CURTATE CYCLOID if Q is outside. The equations of such a cycloid ar $x = a\theta - b\sin\theta$, $y = a - b\cos\theta$ when $b = BQ$.

Epicycloid (or **hypocycloid**) is a curve traced by a point on the circum ference of a circle which rolls without slipping on the outside (or inside) of a fixed circle. Let the radius of the fixed circle $= R$, radius of rolling circle $= r$ The parametric equations are:

Epicycloid (Fig. 179). $x = (R + r)\cos\theta - r\cos(\theta + R\theta/r)$, $y = (R + r)$ $\sin\theta - r\sin(\theta + R\theta/r)$. **Hypocycloid** (Fig. 180), the same, with the sign of r changed. Parameter θ = the angle described by the line of centers

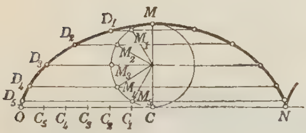

FIG. 178.

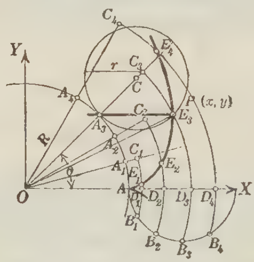

FIG. 179.

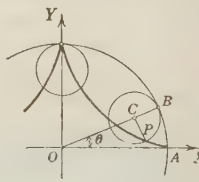

FIG. 180.

measured from a position when the tracing point is on the fixed circle. Th normal to the curve for any position of the tracing point passes through th point of contact of the circles. (E_3A_3, Fig. 179.)

Construction of epicycloid (Fig. 179). Arcs AA_1, AA_2, etc., on the fixed circle equa arcs AB_1, AB_2, etc. on the rolling circle. Arcs B_1C_1, B_2C_2, etc., are drawn with O as cente and $D_1B_1 = C_1E_1$, $D_2B_2 = C_2E_2$, etc. A similar construction holds for the hypocycloid.

Epitrochoid (or **Hypotrochoid**) is the curve traced by a point (Fig. 17 or 180), on the radius of the rolling circle at a fixed distance b from its center The parametric equations of the curve are,

$$x = (R + r)\cos\theta - b\cos(\theta + R\theta/r),$$

$$y = (R + r)\sin\theta - b\sin(\theta + R\theta/r).$$

(For a hypotrochoid change signs of r and b.) If $R = 2r$, the hypocycloi is a diameter of the fixed circle, and the hypotrochoid is an ellipse. If $R = 4r$ the hypocycloid has four cusps and is called the ASTROID (Fig. 181). Its rect angular equation is $x^{2/3} + y^{2/3} = R^{2/3}$. If $R = 2r$, the epicycloid is the CAR DIOID. (Fig. 182.) When each chord drawn from a fixed point of a circle i produced a distance equal to the diameter, the extremities will lie on a car dioid.

The polar equation of the cardioid is $\rho = a(1 + \cos\theta)$; (Fig. 182). The rectangular equation is $(x^2 + y^2 - ax)^2 = a^2(x^2 + y^2)$.

Involute of a circle is the curve traced by the end of a taut string wrapped around a fixed circle and unwinding. The parametric equations are (Fig. 183),

$$x = r\cos\theta + r\theta\sin\theta;\quad y = r\sin\theta - r\theta\cos\theta,\ (\theta \text{ in radians}).$$

At any instant the portion of string unwound (as BP) is normal to the involute and tangent to the circle, and $BP = arc\ AB$.

Catenary is the curve assumed by a flexible cord of uniform density when suspended at its extremities. Its equation (Fig. 184) is $y = a\cosh(x/a)$. (Table 21.) The constant a equals the ratio of the horizontal component of tension in the cord to the weight of cord per unit length. The length of the normal drawn from $P(x, y)$ on the curve and intercepted by $OX = y^2/a$.

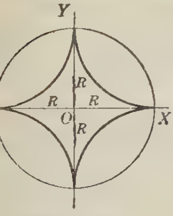

Fig. 181.

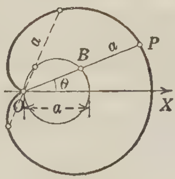

Fig. 182.

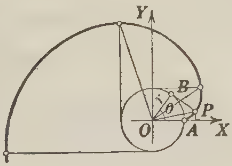

Fig. 183.

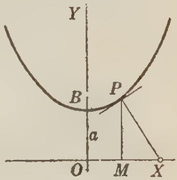

Fig. 184.

Spiral of Archimedes is the curve traced by a point moving with constant speed v on a line which turns about a fixed point on itself with uniform angular velocity w. (Fig. 185.) The polar equation is $\rho = a\theta$ (θ in radians), where $a = v/w$, w being expressed in radians per sec., or $\rho = b\theta/360°$ (θ in degrees, $b = 2\pi a$).

To construct the curve, draw radial lines OR_1, OR_2, OR_3, etc., forming angles α, 2α, 3α, etc., with OX; lay off $OP_1 = a\alpha$ (α in radians) $= b\alpha/360$ (α in degrees), $OP_2 = 2OP_1$, $OP_3 = 3OP_1$, etc. Consecutive coils of the spiral intercept equal lengths ($2\pi a$) on any radius. The normal at any point P cuts off a constant distance a from O on a line ON drawn perpendicular to OP.

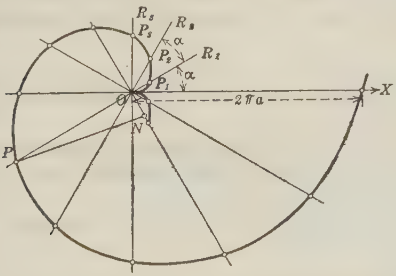

Fig. 185.

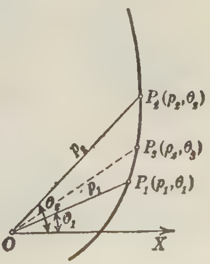

Fig. 186.

Logarithmic spiral is a curve cutting all radii drawn to it from a fixed point at the same angle. The polar equation is, $\rho = be^{a\theta}$ (θ in radians). (Fig. 186.) The cotangent of the angle between radius OP_1 and the tangent at P_1 equals a. The radius equals b when $\theta = 0$. If P_1 and P_2 are points on the

curve, and angle P_1OP_2 is bisected and OP_3 is laid off on this bisector equal to the mean proportional between OP_1, and OP_2 ($OP_3 = \sqrt{OP_1 \cdot OP_2}$), then P_3 is on the curve. For negative values of θ increasing numerically, the spiral winds about O with decreasing radius.

To construct a normal at P, lay off on OP from P a length equal to 1, at this point erect a perpendicular to OP of length a, then the normal passes through the end of this perpendicular.

A helix is the path of a point which moves on a right circular cylinder of radius r at constant speed v parallel to the axis and at the same time rotates about the axis with uniform angular velocity w (radians per sec.). The curve cuts all elements at an angle A whose tangent equals rw/v. Consecutive coils intercept equal lengths $h(= 2\pi r \cot A)$ on an element. The length of a helix for one complete turn equals $2\pi r/\sin A$. The curve formed by a screw thread is a helix, and h = the pitch of the thread.

CALCULUS

55. Functions

Definitions. When two variables x and y are so related that the value of y depends on the value of x, then y is said to be a FUNCTION of x. The functional relation is written $y = f(x)$ [read f of x]. If $x = x_0$ gives a corresponding value of y as y_0, then $y_0 = f(x_0)$. The GRAPH OF A FUNCTION is the curve obtained by plotting corresponding values of x and y as rectangular co-ordinates (Art. 11). A mathematical expression containing a variable is a FUNCTION of this variable. In $y = f(x)$, x is called the INDEPENDENT VARIABLE, y the DEPENDENT variable.

From $y = \log_e x$, it follows that $x = e^y$ (Art. 15). Functions $\log_e x$ and e^y are called INVERSE FUNCTIONS.

An INCREMENT of a variable is an increase (+) or a decrease (−) in its value. Increment of x is denoted by Δx (read "*delta* x"), of y by Δy; etc. When values of the independent variable (x) and its increment (Δx) are given, the increment of dependent variable $y = f(x)$ is $\Delta y = f(x + \Delta x) - f(x)$, that is Δy is the difference of the values of the function for the two values ($x + \Delta x$ and x) of the independent variable.

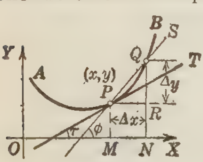

FIG. 187.

Example. If $y = 2 \sin x$, the increment of y when $x = 30°$ and $\Delta x = 2°$ is $\Delta y = 2 \sin 32° - 2 \sin 30° = 2(0.5299 - 0.5000) = 0.060$.

The RATIO OF CORRESPONDING INCREMENTS $\Delta y/\Delta x$ is the slope of the secant drawn through points on the graph of the function with co-ordinates (x, y) $(x + \Delta x, y + \Delta y)$. Thus, in Fig. 187, $\Delta y/\Delta x = RQ/PR = \tan \angle RPQ$ = the slope of the secant line PS through $P(x, y)$ and $Q(x + \Delta x, y + \Delta y)$.

56. Derivatives

The derivative of a function is obtained by calculating the ratio of corresponding increments of the function and independent variable and finding the LIMITING VALUE of this ratio when the increment of the independent variable decreases numerically and becomes zero. The fact that a variable as Δx

decreases numerically and becomes zero is written $\Delta x \doteq 0$ (read Δx approaches zero as a limit).

Notation for derivative of y with respect to x is dy/dx (or $D_x y$). From the above definition, $\frac{dy}{dx}$ = the limiting value of $\left(\frac{\Delta y}{\Delta x}\right)$ when $\Delta x \doteq 0$, or $\underset{\Delta x \doteq 0}{\text{Limit}} \left(\frac{\Delta y}{\Delta x}\right)$, as it is usually abbreviated.

Notation for derivative of $f(x)$ with respect to x is

$$\frac{d}{dx} f(x) = f'(x) = \underset{\Delta x \doteq 0}{\text{Limit}} \left(\frac{f(x + \Delta x) - f(x)}{\Delta x}\right).$$

This equation shows formally the steps necessary to calculate the derivative of a function. For actual work formulas for derivatives (or DIFFERENTIALS) are at hand, and those given below suffice for engineering problems.

Slope of tangent at a point on the graph of $y = f(x)$ is given immediately by the derivative of the function, that is, the value of the derivative for a given value of x equals the tangent of the angle formed with the X-axis by the line drawn tangent to the graph at the corresponding point.

In Fig. 187 when $\Delta x = 0$, the point Q takes successive positions on the arc PQ nearer P, the secant PS turns about P, and, eventually, when Δx becomes zero, secant PS becomes tangent to the graph at P, its slope becoming, in the limit, the slope of PT.

Formulas for derivatives, in which c, n, are constants, e the Napierian base (Art. 15), and u, v, w, are functions of x.

(1) $\frac{dc}{dx} = 0.$

(2) $\frac{dx}{dx} = 1.$

(3) $\frac{d}{dx}(u + v - w) = \frac{du}{dx} + \frac{dv}{dx} - \frac{dw}{dx}.$

(4) $\frac{d}{dx}(cv) = c\frac{dv}{dx}.$

(5) $\frac{d}{dx}(uv) = u\frac{dv}{dx} + v\frac{du}{dx}.$

(6) $\frac{d}{dx}(v)^n = n(v)^{n-1}\frac{dv}{dx}.$

(7) $\frac{d}{dx}\left(\frac{u}{v}\right) = \frac{1}{v^2}\left(v\frac{du}{dx} - u\frac{dv}{dx}\right).$

(8) $\frac{d}{dx}\log_e v = \frac{1}{v}\frac{dv}{dx}.$

(9) $\frac{d}{dx}\log_{10} v = \frac{\log_{10} e}{v}\frac{dv}{dx}.$

(10) $\frac{d}{dx}e^v = e^v\frac{dv}{dx}.$

(11) $\frac{d}{dx}c^v = c^v \log_e c \frac{dv}{dx}.$

(12)* $\frac{d}{dx}\sin v = \cos v\frac{dv}{dx}.$

(13)* $\frac{d}{dx}\cos v = -\sin v\frac{dv}{dx}.$

(14)* $\frac{d}{dx}\tan v = \sec^2 v\frac{dv}{dx}.$

(15)* $\frac{d}{dx}\cot v = -\csc^2 v\frac{dv}{dx}.$

(16)* $\frac{d}{dx}\sec v = \sec v \tan v\frac{dv}{dx}.$

(17)* $\frac{d}{dx}\csc v = -\csc v \cot v\frac{dv}{dx}.$

(18) $\frac{d}{dx}\sin^{-1} v = \frac{1}{\sqrt{1 - v^2}}\frac{dv}{dx}.$

(19) $\frac{d}{dx}\cos^{-1} v = -\frac{1}{\sqrt{1 - v^2}}\frac{dv}{dx}.$

(20) $\frac{d}{dx}\tan^{-1} v = \frac{1}{1 + v^2}\frac{dv}{dx}.$

* In 12–17, v must be measured in radians.

(21) $\dfrac{d}{dx}\cot^{-1} v = -\dfrac{1}{1+v^2}\dfrac{dv}{dx}.$

(22) $\dfrac{d}{dx}\sec^{-1} v = \dfrac{1}{v\sqrt{v^2-1}}\dfrac{dv}{dx}.$

(23) $\dfrac{d}{dx}\csc^{-1} v = -\dfrac{1}{v\sqrt{v^2-1}}\dfrac{dv}{dx}.$

(24) $\dfrac{d}{dx}\sinh v = \cosh v\dfrac{dv}{dx}.$

(25) $\dfrac{d}{dx}\cosh v = \sinh v\dfrac{dv}{dx}.$

(26) $\dfrac{d}{dx}\tanh v = \text{sech}^2\, v\dfrac{dv}{dx}.$

(27) $\dfrac{d}{dx}\coth^2 v = -\text{csch}^2\, v\dfrac{dv}{dx}.$

(28) $\dfrac{d}{dx}\text{sech}\, v = -\text{sech}\, v\tanh v\dfrac{dv}{dx}.$

(29) $\dfrac{d}{dx}\text{csch}\, v = -\text{csch}\, v\coth v\dfrac{dv}{dx}.$

(30) $\dfrac{d}{dx}\sinh^{-1} v = \dfrac{1}{\sqrt{v^2+1}}\dfrac{dv}{dx}.$

(31) $\dfrac{d}{dx}\cosh^{-1} v = \dfrac{1}{\sqrt{v^2-1}}\dfrac{dv}{dx}.$

(32) $\dfrac{dv}{dx} = \dfrac{dv}{dt}\cdot\dfrac{dt}{dx}.$

(33) $\dfrac{dv}{dx} = 1\Big/\dfrac{dx}{dv}.$

Differentiation of a function is accomplished by applying in succession formulas from the above list.

Examples. (1) Find $\frac{d}{dx}3\sqrt{9+x^2}$. Apply (4) with $c = 3$, $v = \sqrt{9+x^2}$; the result is $3\frac{d}{dx}\sqrt{9+x^2}$. Change the square root to the power ½ and apply (6) with $v = 9 + x^2$, $n = \frac{1}{2}$. This gives $3 \times \frac{1}{2}(9+x^2)^{-\frac{1}{2}}\frac{d}{dx}(9+x^2)$. Now apply (3). $\frac{d}{dx}(9+x^2) = \frac{d}{dx}9 + \frac{d}{dx}x^2$. By (1) $\frac{d}{dx}9 = 0$, and by (6) and (2) $\frac{d}{dx}x^2 = 2x$. The final result is $3x(9+x^2)^{-\frac{1}{2}}$, or $3x/\sqrt{9+x^2}$. *Ans.*

(2) Find $\frac{d}{dx}(25\cos x - 12.8\cot x)$. Applying (3), $\frac{d}{dx}(25\cos x) - \frac{d}{dx}(12.8\cot x)$. Apply (5) in each term and then (13) and (15). The result is $-25\sin x + 12.8\csc^2 x$. *Ans.*

Logarithmic differentiation is a method under which the derivative of the Nap log of a function is worked out and this result multiplied by the function, the final product being the derivative of the latter.

Example. Find $\frac{d}{dx}\frac{x}{\sqrt{9-x^2}}$. $\log_e \frac{x}{\sqrt{9-x^2}} = \log_e x - \frac{1}{2}\log_e(9-x^2)$. (See Art. 4) Differentiating this by (3), (4), (8), successively, the result is $\frac{1}{x} + \frac{x}{9-x^2} = \frac{9}{x(9-x^2)}$. Multiplying this by $\frac{x}{\sqrt{9-x^2}}$, the product is $9/(9-x^2)^{\frac{3}{2}}$. *Ans.*

57. Applications of differential calculus

Maximum and minimum values of a function. In Fig. 188, which represents a graph of $f(x)$, the value of $f(x)$ for $x = OM$ is represented by MA, and this value of $f(x)$ is said to be a MAXIMUM, because it is greater than the values of the function immediately preceding or following it. Similarly the function has a MINIMUM value ($= NB$) when $x = ON$. The slope of the graph is zero at A and also at B (horizontal tangents). Passing along the graph through A from left to right, the slope changes sign from + to −

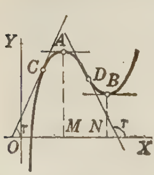

FIG. 188.

while at B, the slope changes sign from $-$ to $+$. Hence $f(x)$ is a maximum for $x = a$ when its derivative vanishes for $x = a$ and changes sign from $+$ to $-$ as x increases through a; $f(x)$ is a minimum for $x = a$ when its derivative vanishes for $x = a$ and changes sign from $-$ to $+$ as x increases through a.

To examine a function for maximum or minimum values, find its derivative, set it equal to zero, and solve this equation for values (CRITICAL VALUES) of the variable. Consider one critical value at a time and determine the sign of the derivative, first for a value of the variable a trifle less than the critical value, and second for a value a trifle greater. Change in sign from $+$ to $-$ shows a maximum value of the function for the particular critical value, of $-$ to $+$, a minimum value.

In many problems the function to be examined must be derived and it is often advisable to graph this function. The conditions of the problem usually determine without testing whether the function is a maximum or a minimum.

Examples. (1) An opening is to be dug from a point A to a point B, 300 ft. lower than A and 500 ft. east of A. On level A the opening is dug through earth, below A through solid rock. The cost through earth is \$1 per linear foot, through rock \$3 per linear foot. Find the distance tunneled on level A for least cost, and find the least cost.

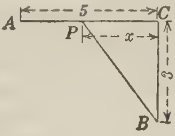

FIG. 189.

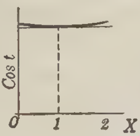

FIG. 190.

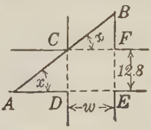

FIG. 191.

In Fig. 189 the distances are marked in hundred feet. The cost of a tunnel from A to P is $100(5 - x)$ dollars, and of the incline from P to B is $100 \times PB \times 3 = 300\sqrt{9 + x^2}$ dollars. Hence the total cost is $100[5 - x + 3\sqrt{9 + x^2}]$ dollars. Fig. 190 shows the graph of this function. For minimum cost the derivative must vanish, hence $\frac{d}{dx}[5 - x + \sqrt{9 + x^2}] = 0$. The result (see Ex. 1, Art. 56) is $-1 + 3x/\sqrt{9 + x^2} = 0$, or $\sqrt{9 + x^2} = 3x$. Squaring and solving for x, $x = \sqrt{9/8} = 3\sqrt{2}/4 = 1.06$. Hence the length of the tunnel section is $500 - 106 = 394$ ft. The length of the inclined part through rock is $\sqrt{9 + 9/8} = 3.18$ hundred feet. The minimum cost is $394 + 954 = \$1348$. *Ans.*

(2) A girder 25 ft. long is moved on rollers along a passageway 12.8 ft. wide and thence into a corridor at right angles to the passageway. Neglecting the width of the girder, how wide must the corridor be?

In Fig. 191, $w = AE - AD = AB \cos x - CD \cot x$, or $w = 25 \cos x - 12.8 \cot x$. When the girder just swings clear, w is a maximum, hence $dw/dx = 0$. This gives (by Ex. 2, Art. 56) $-25 \sin x + 12.8 \csc^2 x = 0$. From Art. 31, $\csc x = 1/\sin x$, hence $\sin^3 x = 12.8/25 = 64/125$. Then $\sin x = 4/5$, and $\cos x = 3/5$, $\cot x = 3/4$, $w = 25(3/5) - 12.8(3/4) = 15 - 9.6 = 5.4$ ft. *Ans.*

Derivatives of higher order arise when the first derivative is differentiated, this result differentiated, etc. The order of a derivative is indicated by the number of times the original function is differentiated. A second derivative is the derivative of the first derivative. The notation is $\frac{d}{dx}\left(\frac{dy}{dx}\right) = \frac{d^2y}{dx^2}$ (second derivative); $\frac{d^3y}{dx^3}, \frac{d^4y}{dx^4}, \ldots, \frac{d^ny}{dx^n}$, third, fourth, . . . , nth, derivative, respectively. For $f(x)$, successive derivatives are indicated by placing an accent on the f, as $f'(x), f''(x), f'''(x), f^{\text{IV}}(x) \ldots f^{(n)}(x)$.

Sign of second derivative for a given value of x determines whether the graph is below the tangent at the corresponding point on the graph, *i.e.*, whether the graph is "concave downward," as at A, Fig. 188, or above the tangent, *i.e.*, "concave upward," as at B, Fig. 188. The rule is, if the value of the second derivative is positive, the graph is concave upward; if negative, the graph is concave downward.

Second test for maximum and minimum values of a function. $f(x)$ is a maximum for $x = a$ if $f'(a) = 0$ and $f''(a)$ is negative, and a minimum if $f'(a) = 0$ and $f''(a)$ is positive. This second test is convenient when the second derivative can be readily calculated.

58. Differentials

Definitions. The DIFFERENTIAL OF A FUNCTION is the product of its derivative by the increment of the independent variable. $d[f(x)] = f'(x)\Delta x$. Then $d(x) = 1 \times \Delta x$ (written $dx = \Delta x$). Also $dy = dy/dx$ times dx. The differential and the increment of an independent variable are identical, but the differential and increment of a function are not. In Fig. 192, when passing from P to P', $\Delta x = MM' = PQ = dx$, increment of function $y = f(x)$ is QP', but the differential of the function is QT, that is the differential of the function is the increment of the ordinate of the tangent to the graph at the point under consideration. Differentials are INFINITESIMALS, that is, variables whose numerical values decrease and ultimately become zero. The preceding definitions give the derivative equal to the quotient of corresponding differentials dy and dx (a DIFFERENTIAL QUOTIENT). The differential of a function is the principal part of its increment. The ratio of the increment to the differential becomes unity when the increment of the variable becomes zero. In problems involving infinitesimals, the increment of a function is replaced by its differential. This principle of replacing the increment by its differential has wide application in calculus. More generally, one infinitesimal may be replaced by another if the limit of their ratio is unity.

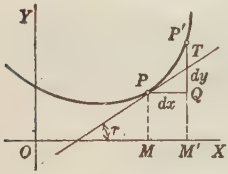

FIG. 192.

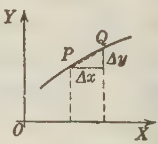

FIG. 193.

Example. Find the differential of the arc of a curve. Passing from P to Q along the curve (Fig. 193), the increment of arc is arc $PQ = \Delta s$. The chord $PQ = \sqrt{(\Delta x)^2 + (\Delta y)^2}$. When $\Delta x \doteq 0$, the ratio of arc PQ to chord PQ becomes unity. Hence chord PQ may be replaced by Δs, this by ds, and Δx and Δy by dx and dy, respectively. Hence $ds = \sqrt{dx^2 + dy^2}$. *Ans.*

Differential of arc s of a curve. In rectangular co-ordinates, $ds = \sqrt{dx^2 + dy^2} = \sqrt{1 + (dy/dx)^2}\ dx = \sqrt{1 + (dx/dy)^2}\ dy$. In polar coordinates $ds = \sqrt{d\rho^2 + \rho^2 d\theta^2} = \sqrt{\rho^2 + (d\rho/d\theta)^2}\, d\theta$.

59. Small errors

If an error h is made in measuring x, the corresponding error in calculating $f(x)$ is $f(x + h) - f(x)$ = increment of $f(x)$. When h is numerically small, the increment of the function may be replaced by its differential, that is, *error in $f(x) = f'(x)$ times error in x.* This formula determines the degree of approximation in value of a function when the degree of accuracy of the measurement of the variable is known.

Example. An angle x is measured as 45° with a possible error of $\pm$ 1′. What is the corresponding error in tan x? *Solution.* The error in tan $x = \frac{d}{dx}$ (tan x) times the error in x (in radians) = sec² x times *error in x*. By Table 11, 1′ = 0.000291 rad. Sec² 45° = 2. Hence the required error is $\pm$ 0.000582 unit, that is, tan x lies between 0.999 and 1.001, using three decimal places.

Probable error of $y = f(x)$ is $f'(x)$ *times the probable error in* x. (Art. 22.)

60. Rates

In Fig. 192 rate of change of y along the tangent PT per unit change in x is constant and equals numerically the slope of the tangent. But the rate of change of the function at P (instantaneous rate) per unit change in x is the same as the rate of change at y along the tangent at P. This gives an interpretation of dy/dx as a rate, namely, rate of change in y per unit change in x. This fact in connection with derivatives is of great importance in applied science.

Examples. (1) The velocity of a point moving along a line at a distance x from a fixed point on that line is dx/dt, (variable t representing time), since VELOCITY is the rate of change of distance per unit change in time (time rate of change of distance). ACCELERATION $= dv/dt$, the time-rate of change of velocity.

(2) Sand pouring from a chute at the rate of 50 cu. ft. per min. forms a conical pile whose base has a diameter always equal to its height. How rapidly is the height of the pile increasing when it is 10 ft. high?

In Fig. 194 the volume of the pile $= V = \frac{1}{3}\pi x \cdot x^2/4$ (Art. 30). Hence $V = \pi x^3/12$. Differentiating with respect to t, the result is $\frac{dV}{dt} = \pi/12 \times 3x^2 dx/dt$. Now dV/dt = time-rate of change of volume = 50 cu. ft. per min. (from the given data), and x = 10 ft. Also dx/dt is the rate at which the height of the pile is increasing per unit time. This is the unknown sought. Solving, $dx/dt = 4\frac{dV}{dt}/\pi x^2 = 200/100\pi = 0.64$ ft. per min. *Ans.*

61. Curvature

Definitions. The CURVATURE OF A CURVE relates to the rate at which a point describing the curve changes the direction of its motion. In mathematical terms, CURVATURE AT A POINT is the rate of change of the angle which the tangent forms with a fixed line per unit arc on the curve (arc-rate of change of direction). In Fig. 195 the tangent turns through angle Δi as P moves to P', a distance Δs along the curve. The curvature at $P = di/ds$. Angle i is measured in radians, and curvature is therefore expressed in radians per unit length of arc. The CURVATURE OF A CIRCLE is the same at all points and equals the reciprocal of the radius, numerically. CIRCLE OF CURVATURE (Fig. 196) at point P on a curve is the circle tangent at P whose curvature equals that of the curve at P. The center of this circle is the CENTER OF CURVATURE of the curve. The circle of curvature crosses the curve at the point of contact.

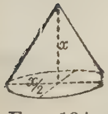

FIG. 194.

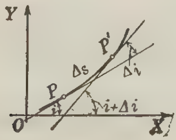

FIG. 195.

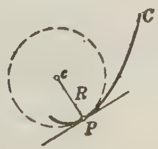

FIG. 196.

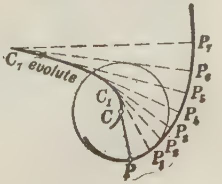

FIG. 197.

Formulas for curvature

Rectangular co-ordinates. K = curvature, R = radius of curvature, (a, b) = center of curvature, $p = dy/dx$, $q = d^2y/dx^2$.

$K = q/(1 + p^2)^{3/2}$. $R = 1/K$. $a = x - p(1 + p^2)/q$. $b = y + (1 + p^2)/q$.

Polar co-ordinates. $s = d\rho/d\theta$, $t = d^2\rho/d\theta^2$.

$K = (\rho^2 - t\rho + 2s^2)/(\rho^2 + s^2)^{3/2}$. $R = 1/K$.

The point of intersection of normals drawn at consecutive points $P(x, y)$ and $Q(x + \Delta x, y + \Delta y)$ approches the center of curvature at P when Q moves along the curve toward P.

Evolute of a curve (Fig. 197) is the locus of the centers of curvature of that curve. To find the equation of the evolute from the rectangular equation of the curve, work out expressions for a and b by the formulas given above, and eliminate x and y from these equations by means of the equation of the given curve.

Formulas for radii of curvature (R) for standard curves, and their evolutes

Parabola $(y^2 = 2px)$. $R = (p + 2x)^{3/2}/\sqrt{p} = (p^2 + y^2)^{3/2}/p^2$ at (x, y).
Evolute $27py^2 = 8(x - p)^3$.

Ellipse $(b^2x^2 + a^2y^2 = a^2b^2)$. $R = (b^4x^2 + a^4y^2)^{3/2}/a^4b^4$ at (x, y).
Evolute $(ax)^{2/3} + (by)^{2/3} = (a^2 - b^2)^{2/3}$.

Hyperbola $(b^2x^2 - a^2y^2 = a^2b^2)$. $R = (b^4x^2 + a^4y^2)^{3/2}/a^4b^4$ at (x, y).
Evolute $(ax)^{2/3} - (by)^{2/3} = (a^2 + b^2)^{2/3}$.

Rectangular hyperbola $(2xy = a^2)$. $R = (x^2 + y^2)^{3/2}/a^2$ at (x, y).
Evolute $(x + y)^{2/3} - (x - y)^{2/3} = 2a^{2/3}$.

Cycloid (equations, Art. 54). $R = 4a \sin \theta/2 = 2AP$ (Fig. 177).
Evolute $x = a(\theta' - \sin \theta')$, $y = a(1 - \cos \theta')$, $(\theta' = \theta + \pi)$, an equal cycloid.

Epicycloid (equations, Art. 54). $R = 4(R' + r)r \sin (R'\theta/2r)/(R' + 2r)$. ($R'$ = the radius of the fixed circle.)

Hypocycloid (equations, Art. 54). $R = 4\,(R' - r)r \sin (R'\theta/2r)/(R' - 2r)$. ($R'$ = the radius of the fixed circle.)

Catenary (Art. 54), $(y = a \cosh x/a)$. $R = y^2/a$, at any point (x, y).

Spiral of Archimedes (Art. 54), ($\rho = a\theta$ [θ in radians]) $R = (\rho^2 + a^2)^{3/2}/(\rho^2 + 2a^2)$.

Logarithmic spiral (Art. 54), $(\rho = be^{a\theta})$ $R = \rho\sqrt{1 + a^2}$.

Properties of an evolute. The normal to a given curve is tangent to the evolute at the corresponding center of curvature. The length of the arc of the evolute between two centers of curvature equals the difference of radii of the circles of curvature of the given curve having these centers.

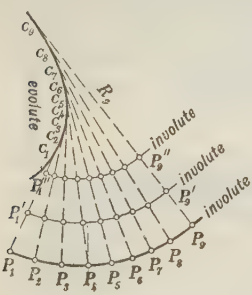

FIG. 198.

In Fig. 197, arc C_1C_7 on the evolute = radius C_7P_7 − radius C_1P_1.

Curves having a given curve as a common evolute are called INVOLUTES of that curve. (Also called PARALLEL CURVES.)

Fig. 198 shows three involutes with a common evolute. If a flexible string is made to take the form of the evolute, and the free end is unwound and kept taut, this end will move along an involute.

62. Series

Definitions. A POWER SERIES consists of an indicated sum of terms each of which is the product of a constant and a positive integral power of a variable, arranged according to ascending powers of the variable, the number of terms being unlimited (INFINITE SERIES).

Example. $1 + \frac{1}{2}x + \frac{1}{3}x^2 + \frac{1}{4}x^3 + \ldots$ *ad infinitum.*

For a given value of the variable, the sum S_n of n (any number of) terms is a function of n. If, as n increases indefinitely, S_n remains finite and approaches a definite value S, that is, if $\underset{n \doteq \infty}{\text{Limit}}\ S_n = S$, then the series is said to be CONVERGENT for this value of the variable and to have a sum equal to S. A power series which is convergent for values of the variable within a certain interval is called a CONVERGENT SERIES. A power series convergent for no value of the variable is called DIVERGENT.

Expansion of a function in a power series is accomplished by means of the following formulas.

Taylor's series

Powers of $(x - a)$, where a is a given value of x.

$$f(x) = f(a) + f'(a)(x - a) + f''(a)\frac{(x-a)^2}{1\cdot 2} + f'''(a)\frac{(x-a)^3}{1\cdot 2\cdot 3} + \ldots + f^n(a)\frac{(x-a)^n}{n!} + \ldots$$

Maclaurin's series

Powers of x.

$$f(x) = f(o) + f'(o)x + f''(o)\frac{x^2}{1\cdot 2} + f'''(o)\frac{x^3}{1\cdot 2\cdot 3} + \ldots + f^{(n)}(o)\frac{x^n}{n!} + \ldots.$$

Such an expansion is valid only for values of x for which the series is convergent. Determination of the interval of convergence of a given series is a necessary precaution before using it instead of the function in numerical calculations. (See below where the interval of convergence is given for many series.) Expansion of a function as a polynomial of nth degree with a remainder is given by Taylor's Series using first $(n + 1)$ terms and adding the REMAINDER TERM, $f^{(n+1)}(z)x^{n+1}/(n + 1)!$, where the value of z lies between a and x. This polynomial gives an approximate representation of the function for those values of x for which the remainder term is numerically less than the limit of error determined by the problem in hand.

Alternating series have the characteristic that successive terms have opposite signs. Such a series converges if successive terms decrease in numerical value and tend toward a limit zero. The sum is then less than the first term.

Convergent power series. The interval of convergence is written after each series.

1. **Binomial Series** (Theorem) — Interval of convergence

$$(1+x)^{-1/2} = 1 - \tfrac{1}{2}x + \frac{1\cdot 3}{2\cdot 4}x^2 - \frac{1\cdot 3\cdot 5}{2\cdot 4\cdot 6}x^3 + \ldots \qquad x^2 < 1.$$

$$(a+bx)^{-1} = \frac{1}{a}\left(1 - \frac{bx}{a} + \frac{b^2x^2}{a^2} - \frac{b^3x^3}{a^3} + \ldots\right) \qquad b^2x^2 < a^2.$$

$$(1+x)^n = 1 + nx + \frac{n(n-1)}{2!}x^2 + \frac{n(n-1)(n-2)}{3!}x^3 + \ldots \qquad x^2 < 1$$

2. $$e^x = 1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} + \ldots + \frac{x^n}{n!} + \ldots \qquad \text{all values of } x.$$

3. $$\sin x = x - \frac{x^3}{3!} + \frac{x^5}{5!} - \frac{x^7}{7!} + \ldots \qquad \text{all values of } x.$$

4. $$\cos x = 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \frac{x^6}{6!} + \ldots \qquad \text{all values of } x.$$

5. $$\tan x = x + \frac{x^3}{3} + \frac{2}{15}x^5 + \frac{17}{315}x^7 + \ldots \qquad x^2 < \tfrac{1}{4}\pi^2.$$

6. $$\log_e x = 2\left(\frac{x-1}{x+1} + \frac{1}{3}\left(\frac{x-1}{x+1}\right)^3 + \frac{1}{5}\left(\frac{x-1}{x+1}\right)^5 + \ldots\right) \qquad x > 0.$$

7. $$\sec x = 1 + \frac{x^2}{2!} + \frac{5x^4}{4!} + \frac{61x^6}{6!} + \ldots \qquad x^2 < \tfrac{1}{4}\pi^2$$

8. $$\sin^{-1} x = x + \frac{1}{6}x^3 + \frac{1\cdot 3}{2\cdot 4}\frac{x^5}{5} + \frac{1\cdot 3\cdot 5}{2\cdot 4\cdot 6}\frac{x^7}{7} + \ldots \qquad x^2 < 1.$$

9. $$\tan^{-1} x = x - \tfrac{1}{3}x^3 + \tfrac{1}{5}x^5 - \tfrac{1}{7}x^7 + \ldots. \qquad x^2 < 1.$$

10. $$\sinh x = x + \frac{x^3}{3!} + \frac{x^5}{5!} + \frac{x^7}{7!} + \ldots \qquad \text{all values of } x.$$

11. $$\cosh x = 1 + \frac{x^2}{2!} + \frac{x^4}{4!} + \frac{x^6}{6!} + \ldots \qquad \text{all values of } x.$$

An approximate formula for a function results when the function is set equal to a finite number of terms of its expansion in a convergent series. Such a formula holds with a certain degree of exactness for values of the variable for which the series is convergent. If the series is alternating, the error is less than the term in the series following the last term in the formula used.

Example. $1/\sqrt{1+x} = 1 - \tfrac{1}{2}x$ for $x^2 < 1$. The error is numerically less than $3x^2/8$. This result follows directly from the first series given above.

Computation by series is often a useful means of calculation when Tables are not at hand, or when the degree of approximation desired exceeds that given in Tables, or obtainable by the logarithms which are accessible.

Example. Calculate $(34)^{2/5}$ to four decimal places. The nearest fifth power to 34 is $32 = 2^5$. Write the required quantity $(32 + 2)^{2/5} = (32(1 + 1/16))^{2/5} = (32)^{2/5}(1 + 1/16)^{2/5} = 4(1 + 1/16)^{2/5}$. Now $(1 + x)^{2/5} = 1 + 2x/5 - 3x^2/25 + 8x^3/125 - 26x^4/625 +$ etc. Put $x = 1/16$. Then $(34)^{2/5} = 4 + 0.1 - 0.001875 + 0.0000625 - 0.000003 + \ldots$ Taking 4 terms, the result is 4.0981875 and the error is less than the fifth term 0.000003. Hence 4.09818 is correct to five decimal places. (See Table 27.)

63. Partial derivatives

A function of several independent variables $x, y, z, \ldots$ is represented by $f(x, y, z, \ldots)$. Derivatives may be formed by varying one variable only, and are called PARTIAL DERIVATIVES. NOTATION: $\delta f/\delta x$, $\delta f/\delta y$, $\delta f/\delta z$, etc., or D_xf, D_yf, D_zf, etc. The TOTAL DIFFERENTIAL is $df = \frac{\delta f}{\delta x}dx + \frac{\delta f}{\delta y}dy + \frac{\delta f}{\delta z}dz + \ldots$

When the independent variables receive increments dx, dy, dz, etc., the PRINCIPAL PART of the increment of the function is df. When $x, y, z \ldots$ are functions of the same variable t, the TOTAL DERIVATIVE of f with respect to t is

$$\frac{df}{dt} = \frac{\delta f}{\delta x}\frac{dx}{dt} + \frac{\delta f}{\delta y}\frac{dy}{dt} + \frac{\delta f}{dz}\frac{dz}{dt} + \cdots .$$

This formula gives the rate of change of a function in terms of the rates of change of the independent variables.

Small errors. When the value of a function is determined by measurement of several variables $x, y, z, \ldots$ with small errors $dx, dy, dz, \ldots$, the corresponding error df in the function is given by the above formula for total differential df.

Example. Two sides x, y of a triangle are 81.25 in., 91.04 in., respectively, with possible errors $\pm$ .01 in. in each. The included angle C is 30° with a possible error of 1′. Find the maximum error possible in the area.

Solution. Area $= u = \frac{1}{2}xy \sin C$ (Art. 29). Form du by the above formula. Then $du = \frac{1}{2}y \sin C\,dx + \frac{1}{2}x \sin C dy + \frac{1}{2}xy \cos C dC$. Substitute $x = 81.25$, $y = 91.04$, $dx = dy = .01$, $\sin C = 0.5$, $\cos C = 0.8660$, $dC = 0.0002909$ (radians in 1′). Result is $du = 1.36$ sq. in. *Ans.* Note that the area computed by the given values is 1850 sq. in.

Percentage error is the relative error du/u(d Nap log u) times 100.

In the above example, $du/u = dx/x + dy/y + \cot CdC$, that is, the relative error in area equals the sum of the relative errors in measurements of the sides x and y increased by the relative error in sin C. (See Art. 2.) With the same absolute error in reading the angle C, the relative error in the value of sin C decreases as C increases. For the values given, $du/u = 0.000735$. Hence the percentage error is 7/100 of 1 per cent.

The probable error e of a function $f(x, y, z, \ldots)$ in terms of the probable errors e_1, e_2, e_3 . . . of measured quantities x, y, z, is given by formula

$$e = \sqrt{(\delta f/\delta x)^2 e_1^2 + (\delta f/\delta y)^2 e_2^2 + (\delta f/\delta z)^2 e_3^2 + \cdots}.$$

INTEGRAL CALCULUS

64. Integration

Definitions. INTEGRATION is the process of finding a function of which a given function is the derivative, hence it is the inverse of differentiation. The sign of integration is $\int$ read "*integral of.*" The process is indicated by writing the integral sign before the given function multiplied by the differential of the variable.

Example. $\int 6xdx = 3x^2$, since $\frac{d}{dx}(3x^2) = 6x$. Also $\int 6xdx = 3x^2 + C$, where C is any constant, called the CONSTANT OF INTEGRATION.

Integration is accomplished by reference to a Table of Integrals. The given integral is compared with one of similar form in the table, and, if necessary, made identical with this by simple substitutions. The examples given below illustrate the method.

65. Table of integrals*

General forms

(1) $\int d[f(x)](dx = f(x).$

(2) $\int cf(x)dx = c\int f(x)dx$, where c is a constant.

(3) $\int (u + v)dx = \int udx + \int vdx.$

(4) $\int udv = uv - \int vdu.$

Remark. Formula 4, "integration by parts" is very useful. It may be written

$$\int h(x)d[f(x)] = h(x)f(x) - \int f(x)d[h(x)].$$

The integral remaining in the right-hand member may often be found in tables when the original integral is not. In applying the formula, the given integrand is to be factored into the product of a function $h(x)$ by the differential of another function $f(x)$.

Integrals involving $a + bx$

(5) $\int (a + bx)^n dx = \dfrac{(a + bx)^{n+1}}{b(n + 1)}$, unless $n = -1$, then use (6).

(6) $\int \dfrac{dx}{a + bx} = \dfrac{1}{b}$ Nap log $(a + bx)$.

(7) $\int \dfrac{xdx}{a + bx} = \dfrac{1}{b^2}[a + bx - a$ Nap log $(a + bx)]$.

(8) $\int \dfrac{x^2dx}{a + bx} = \dfrac{1}{b^3}[\tfrac{1}{2}(a + bx)^2 - 2a(a + bx) + a^2$ Nap log $(a + bx)]$.

(9) $\int \dfrac{dx}{x(a + bx)} = -\dfrac{1}{a}$ Nap log $\dfrac{a + bx}{x}$.

(10) $\int \dfrac{xdx}{(a + bx)^2} = \dfrac{1}{b^2}\left[\text{Nap log } (a + bx) + \dfrac{a}{a + bx}\right]$.

* The constant of integration C should be added to the right-hand member in every formula. a, b, c, m, n, p, are constants.

(11) $$\int \frac{x^2 dx}{(a+bx)^2} = \frac{1}{b^3}\left[a + bx - 2a \text{ Nap log } (a+bx) - \frac{a^2}{a+bx}\right].$$

(12) $$\int x\sqrt{a+bx}\,dx = -\frac{2(2a-3bx)\sqrt{(a+bx)^3}}{15b^2}.$$

(13) $$\int \frac{dx}{x\sqrt{a+bx}} = \frac{1}{\sqrt{a}} \text{ Nap log } \frac{\sqrt{a+bx}-\sqrt{a}}{\sqrt{a+bx}+\sqrt{a}}, \text{ for } a > 0.$$

(14) $$\int \frac{dx}{x\sqrt{a+bx}} = \frac{2}{\sqrt{-a}} \tan^{-1}\sqrt{\frac{a+bx}{-a}}, \text{ for } a < 0.$$

(15) $$\int \frac{x\,dx}{\sqrt{a+bx}} = -\frac{2(2a-bx)}{3b^2}\sqrt{a+bx}.$$

(16) $$\int \frac{\sqrt{a+bx}\,dx}{x} = 2\sqrt{a+bx} + a\int \frac{dx}{x\sqrt{a+bx}}.$$

(17) $$\int \frac{x^n dx}{\sqrt{a+bx}} = \frac{2x^n\sqrt{a+bx}}{b(2n+1)} - \frac{2an}{b(2n+1)}\int \frac{x^{n-1}dx}{\sqrt{a+bx}}.$$

(18) $$\int \frac{dx}{x^n\sqrt{a+bx}} = -\frac{\sqrt{a+bx}}{(n-1)ax^{n-1}} - \frac{(2n-3)b}{2(n-1)a}\int \frac{dx}{x^{n-1}\sqrt{a+bx}},$$ unless $n = -1$, then see 13, 14.

Integrals involving $a^2 - x^2$, or $x^2 - a^2$, or $x^2 + a^2$

(19) $$\int \frac{dx}{a^2 - b^2x^2} = \frac{1}{2ab} \text{ Nap log } \frac{a+bx}{a-bx}.$$

(20) $$\int \frac{dx}{a^2 + b^2x^2} = \frac{1}{ab} \tan^{-1}\frac{bx}{a}.$$

(21) $$\int \frac{dx}{\sqrt{a^2 - x^2}} = \sin^{-1}\frac{x}{a}.$$

(22) $$\int \frac{dx}{\sqrt{x^2 \pm a^2}} = \text{Nap log } (x + \sqrt{x^2 \pm a^2}).$$

(23) $$\int \frac{dx}{\sqrt{x^2 + a^2}} = \sinh^{-1}\frac{x}{a}.$$

(24) $$\int \frac{dx}{\sqrt{x^2 - a^2}} = \cosh^{-1}\frac{x}{a}.$$

(25) $$\int x(a+bx^2)^p dx = \frac{(a+bx^2)^{p+1}}{2b(p+1)},$$ unless $p = -1$, then use (26).

(26) $$\int \frac{x\,dx}{a+bx^2} = \frac{1}{2b} \text{ Nap log } (a+bx^2).$$

(27) $\int \sqrt{a^2 - x^2}\, dx = \tfrac{1}{2}x\sqrt{a^2 - x^2} + \tfrac{1}{2}a^2 \sin^{-1}\frac{x}{a}.$

(28) $\int \sqrt{x^2 \pm a^2}\, dx = \tfrac{1}{2}x\sqrt{x^2 \pm a^2} \pm \tfrac{1}{2}a^2 \text{ Nap. log } (x + \sqrt{x^2 \pm a^2}).$

(29) $\int \frac{dx}{x\sqrt{x^2 - a^2}} = \frac{1}{a}\cos^{-1}\frac{a}{x}.$

(30) $\int \frac{dx}{x\sqrt{a^2 \pm x^2}} = -\frac{1}{a}\text{Nap log}\left(\frac{a + \sqrt{a^2 \pm x^2}}{x}\right).$

(31) $\int \frac{\sqrt{a^2 \pm x^2}\, dx}{x} = \sqrt{a^2 \pm x^2} - a \text{ Nap log}\left(\frac{a + \sqrt{a^2 \pm x^2}}{x}\right).$

(32) $\int \frac{\sqrt{x^2 - a^2}\, dx}{x} = \sqrt{x^2 - a^2} - a\cos^{-1}\frac{a}{x}.$

(33) $\int \frac{\sqrt{a^2 - x^2}}{x^2}dx = -\frac{\sqrt{a^2 - x^2}}{x} - \sin^{-1}\frac{x}{a}.$

(34) $\int \frac{\sqrt{x^2 \pm a^2}}{x^2}\, dx = -\frac{\sqrt{x^2 \pm a^2}}{x} + \text{Nap log } (x + \sqrt{x^2 \pm a^2}).$

(35) $\int \frac{x^m dx}{(a^2 - x^2)^{1/2}} = -\frac{x^{m-1}}{m}\sqrt{a^2 - x^2} + \frac{(m-1)a^2}{m}\int \frac{x^{m-2}}{(a^2 - x^2)^{1/2}}dx.$

(36) $\int \frac{x^m dx}{\sqrt{x^2 \pm a^2}} = \frac{x^{m-1}}{m}\sqrt{x^2 \pm a^2} \mp \frac{a^2(m-1)}{m}\int \frac{x^{m-2}dx}{\sqrt{x^2 \pm a^2}}.$

Integrals involving $a + bx + cx^2$

(37) $\int \frac{dx}{a + bx + cx^2} = \frac{2}{\sqrt{4ac - b^2}}\tan^{-1}\frac{2cx + b}{\sqrt{4ac - b^2}},$ when $b^2 < 4ac$.

(38) $\int \frac{dx}{a + bx + cx^2} = \frac{1}{\sqrt{b^2 - 4ac}}\text{ Nap log }\frac{2cx + b - \sqrt{b^2 - 4ac}}{2cx + b + \sqrt{b^2 - 4ac}},$

when $b^2 > 4ac$.

(39) $\int \frac{dx}{\sqrt{a + bx - cx^2}} = \frac{1}{\sqrt{c}}\sin^{-1}\frac{2cx - b}{\sqrt{b^2 + 4ac}}.$

(40) $\int \frac{dx}{\sqrt{a + bx + cx^2}} = \frac{1}{\sqrt{c}}\text{ Nap log } (2cx + b + 2\sqrt{c}\sqrt{a + bx + cx^2}).$

(41) $\int \frac{x\, dx}{a + bx + cx^2} = \frac{1}{2c}\text{ Nap log } (a + bx + cx^2) - \frac{b}{2c}\int \frac{dx}{a + bx + cx^2}.$

(42) $\int \frac{x\, dx}{\sqrt{a + bx + cx^2}} = \frac{1}{c}\sqrt{a + bx + cx^2} - \frac{b}{2c}\int \frac{dx}{\sqrt{a + bx + cx^2}}.$

Other algebraic integrals

(43) $\int x^{n-1}(a + bx^n)^p dx = \frac{(a + bx^n)^{p+1}}{bn(p + 1)}$, unless $p = -1$, then use 44.

(44) $\int \frac{x^{n-1}dx}{a + bx^n} = \frac{1}{nb}$ Nap log $(a + bx^n)$.

Integrals involving transcendental functions

(45) $\int e^{ax}dx = e^{ax}/a.$

(46) $\int a^{nx}dx = a^{nx}/n$ Nap log a.

(47) $\int$ Nap log $nx\, dx = x($Nap log $nx - 1)$.

(48) $\int \sin ax\, dx = -\cos ax/a.$

(49) $\int \cos ax\, dx = \sin ax/a.$

(50) $\int \tan ax\, dx =$ Nap log $\sec ax/a$.

(51) $\int \cot ax\, dx =$ Nap log $\sin ax/a$.

(52) $\int \sec ax\, dx =$ Nap log $(\sec ax + \tan ax)/a$.

(53) $\int \csc ax\, dx =$ Nap log $(\csc ax - \cot ax)/a$.

(54) $\int \sin^2 ax\, dx = \left(\frac{a}{2}x - \frac{1}{4}\sin 2ax\right)/a.$

(55) $\int \cos^2 ax\, dx = \left(\frac{ax}{2} + \frac{1}{4}\sin 2ax\right)/a.$

(56) $\int \tan^2 ax\, dx = \tan ax/a - x.$

(57) $\int \cot^2 ax\, dx = -\cot ax/a - x.$

(58) $\int \sec^2 ax\, dx = \tan ax/a.$

(59) $\int \csc^2 ax\, dx = -\cot ax/a.$

(60) $\int \sec ax \tan ax \, dx = \sec ax/a.$

(61) $\int \csc ax \cot ax \, dx = - \csc ax/a.$

(62) $\int (\sin x)^n dx = -\dfrac{(\sin x)^{n-1} \cos x}{n} + \dfrac{n-1}{n} \int (\sin x)^{n-2} dx.$

(63) $\int (\cos x)^n \, dx = \dfrac{(\cos x)^{\;-1} \sin x}{n} + \dfrac{n-1}{n} \int (\cos x)^{n-2} \, dx.$

(64) $\int (\sin x)^n \cos x \, dx = \dfrac{(\sin x)^{n-1}}{n+1}.$

(65) $\int (\cos x)^n \sin x \, dx = -\dfrac{(\cos x)^{n+1}}{n+1}.$

(66) $\int (\tan x)^n \, dx = \dfrac{(\tan x)^{n-1}}{n-1} - \int (\tan x)^{n-2} \, dx.$

(67) $\int (\cot x)^n \, dx = -\dfrac{(\cot x)^{n-1}}{n-1} - \int (\cot x)^{n-2} dx.$

(68) $\int x e^{ax} dx = \dfrac{e^{ax}}{a^2}(ax - 1).$

(69) $\int x^n e^{ax} dx = \dfrac{x^n e^{ax}}{a} - \dfrac{n}{a} \int x^{n-1} \, e^{ax} dx.$

(70) $\int x^n \text{ Nap} \log x \, dx = x^{n+1}\left[\dfrac{\text{Nap} \log x}{n+1} - \dfrac{1}{(n+1)^2}\right].$

(71) $\int x^m \sin x \, dx = - x^m \cos x + m \int x^{m-1} \cos x \, dx.$

(72) $\int x^m \cos x \, dx = x^m \sin x - m \int x^{m-1} \sin x \, dx.$

(73) $\int e^{ax} \sin nx \, dx = \dfrac{e^{ax} (a \sin nx - n \cos nx)}{a^2 + n^2}.$

(74) $\int e^{ax} \cos nx \, dx = \dfrac{e^{ax} (n \sin nx + a \cos nx)}{a^2 + n^2}.$

(75) $\int \sin^{-1} x \, dx = x \sin^{-1} x + \sqrt{1 - x^2}.$

(76) $\int \cos^{-1} x \, dx = x \cos^{-1} x - \sqrt{1 - x^2}.$

(77) $\int \tan^{-1} x \, dx = x \tan^{-1} x - \tfrac{1}{2} \text{ Nap} \log (1 + x^2).$

(78) $\int \sec^{-1} x\,dx = x \sec^{-1} x - \text{Nap}\log(x + \sqrt{x^2 - 1})$.

(79) $\int \sinh x\,dx = \cosh x$.

(80) $\int \cosh x\,dx = \sinh x$.

(81) $\int \tanh x\,dx = \log\cosh x$.

(82) $\int \coth x\,dx = \log\sinh x$.

For a more extended table, see B. O. Peirce, *A short table of integrals*, by Ginn and Company, Boston, Mass.

Examples in integration

(1) Work out $\int \sqrt{9 - 4x^2}\,dx$.

Since $\sqrt{9 - 4x^2} = 2\sqrt{(3/2)^2 - x^2}$, then $\int \sqrt{9 - 4x^2}\,dx = \int 2\sqrt{(3/2)^2 - x^2}\,dx = 2\int \sqrt{(3/2)^2 - x^2}\,dx$, by (2). The integral remaining is now in the form (27), with $a = 3/2$.
$\therefore \int \sqrt{9 - 4x^2}\,dx = x\sqrt{(3/2)^2 - x^2} + (3/2)^2 \sin^{-1} 2x/3 + C$. *Ans.*

(2) Work out $\int x \sin 2x\,dx$.

This resembles formula 71. Put $v = 2x$, or $x = \frac{1}{2}v$. Hence $dx = \frac{1}{2}dv$. Then $\int x \sin 2x\,dx = \int \frac{1}{2}v \sin v\,\frac{1}{2}dv = \frac{1}{4}\int v \sin v\,dv$, by (2). The remaining integral is now (71), with $m = 1$. Using this and then putting $v = 2x$, the result is $\frac{1}{4}\sin 2x - \frac{1}{2}x\cos 2x + C$. *Ans.*

(3) Work out $\int \frac{x^2dx}{4 - x^2}$.

This example illustrates cases when the division indicated in the integral can be performed. For $x^2/(4 - x^2) = -1 + 4/(4 - x^2)$.
$\therefore \int \frac{x^2dx}{4 - x^2} = -\int dx + 4\int \frac{dx}{4 - x^2} = -x + \text{Nap}\log\frac{2 + x}{2 - x} + C$. *Ans.*

As a rule, in a quotient of two polynomials, divide numerator by denominator when the latter is of lower degree than the former or of the same degree.

66. Constant of integration

Integration by tables gives INDEFINITE INTEGRALS. Two indefinite integrals of a function differ by a constant. The CONSTANT OF INTEGRATION appearing in an indefinite integral takes on a definite value when the data of the problem are properly given.

Example. The slope of a certain curve at any point (x, y) is $-3x/2y$, and the curve passes through (4, 6). Find the equation of curve.

By Art. 56, the slope $= dy/dx$. Hence $dy/dx = -3x/2y$, from which the differential equation $2y\,dy = -3x\,dx$ results. Integrating both members, $y^2 = -3x^2/2 + C$, when C is to be determined so that the curve passes through (4, 6). Putting $x = 4$, $y = 6$, then $36 = -24 + C$, hence $C = 60$. The required equation is $y^2 = -3x^2/2 + 60$, or $3x^2 + 2y^2 - 120 = 0$, an ellipse. *Ans.*

67. Definite integral

Integrating between limits (DEFINITE INTEGRAL) consists in evaluating an indefinite integral for two values of variable x, say $x = b$, and $x = a$, and subtracting the results. The constant of integration then disappears. The notation follows:

If $\int f(x)dx = F(x) + C$, then $\int_a^b f(x)dx = F(b) - F(a)$. b is the UPPER LIMIT; a the LOWER LIMIT. Read the second equation, "integral from a to b of $f(x)\ dx$ equals," etc. Interchanging the limits changes the sign of the definite integral.

68. Applications of integral calculus

Area between the curve $y = f(x)$, the X-axis, and the ordinates at $x = a$, $x = b$ (Fig. 199), such as area $CDPFE$), is given by the definite integral

$$\text{Area} = \int_a^b y\,dx, \text{ when } y = f(x).$$

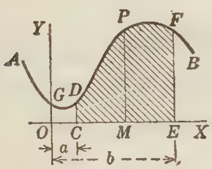

FIG. 199.

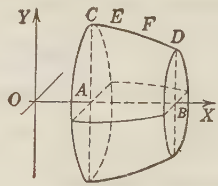

FIG. 200.

Area swept over by radius vector ρ of a curve $\rho = f(\theta)$ (polar equation, Art. 48) turning from $\theta = \alpha$ to $\theta = \beta$ is

$$\text{Area} = \tfrac{1}{2}\int_\alpha^\beta \rho^2 d\theta, \text{ when } \rho = f(\theta).$$

Length of arcs. End-points (x_1, y_1), (x_2, y_2), in rectangular co-ordinates; or (ρ_1, θ_1), (ρ_2, θ_2), in polar co-ordinates.

$$s = \int \sqrt{dx^2 + dy^2} = \int_{x_1}^{x_2} \sqrt{1 + (dy/dx)^2}\,dx = \int_{y_1}^{y_2} \sqrt{(dx/dy)^2 + 1}\,dy.$$

$$s = \int \sqrt{d\rho^2 + \rho^2 d\theta^2} = \int_{\theta_1}^{\theta_2} \sqrt{(d\rho/d\theta)^2 + \rho^2}\,d\theta = \int_{\rho_1}^{\rho_2} \sqrt{1 + (\rho d\theta/d\rho)^2}\,d\rho.$$

The derivative dy/dx, or $d\rho/d\theta$, must be found from the equation (rectangular or polar) of the curve, and the radical reduced to a function of the variable involved in the differential.

Volume of a solid of revolution. Axis of revolution OX, meridian section $y = f(x)$, $x = a$, $x = b$, at extremities of meridian section. (Fig. 200.) $OA = a$, $OB = b$, equation of $CEFD$ is $y = f(x)$,

$$V = \pi \int_a^b y^2 dx.$$

Axis of revolution OY, meridian section $x = h(y)$, $y = c$, $y = d$, at extremities of meridian section.

$$V = \pi \int_c^d x^2 dy.$$

Area of surface of revolution. (x, y) is a point on the meridian section.

$$S = 2\pi \int y \, ds, \text{ or } S = 2\pi \int x \, ds,$$

according to whether the axis of revolution is OX, or OY.

The value of ds is worked out by Art. 58, and the limits of the integral are determined by the co-ordinates of the extremities of the meridian section.

Examples. (1) Find the length of arc of one arch of a cycloid (Art. 54) with the equations $x = a(\theta - \sin \theta)$, $y = a(1 - \cos \theta)$.

Differentiating, $dx = a(1 - \cos \theta)d\theta$, $dy = a \sin \theta \, d\theta$.

Hence $dx^2 + dy^2 = a^2[(1 - \cos \theta)^2 + \sin^2 \theta]d\theta^2 = 2a^2(1 - \cos \theta)d\theta = 4a^2 \sin^2 (\frac{1}{2}\theta) \, d\theta$ (Art. 41).

Then $s = \int \sqrt{dx^2 + dy^2} = \int 2a \sin \frac{1}{2}\theta \, d\theta$. Limits are 0° and 360°.

$$s = -4a \cos \tfrac{1}{2}\theta \Big]_0^{360°} = 4a + 4a = 8a. \quad Ans.$$

(2) Find the volume and surface of the paraboloid, Fig. 201, if $OA = h$, $AB = AD = a$.

The equation of the meridian section OPB is $y^2 = a^2x/h$. Then $V = \pi \int y^2 dx = \pi \int a^2x/h \cdot dx = \pi a^2x^2/2h$, with limits $x = h$, $x = 0$. Hence $V = \pi a^2 h/2$, that is, the area of the base $BDCE$ times half of the height OA.

To find the area of the surface, calculate $ds = \sqrt{1 + (dy/dx)^2} \, dx$. Differentiating $y^2 = a^2x/h$, the result is $2y \, dy/dx = a^2/h$, from which $dy/dx = a^2/2hy$. Hence $ds = \sqrt{1 + a^4/4h^2y^2} \, dx = \sqrt{4h^2y^2 + a^4} \, dx/2hy$.

Then $S = 2\pi \int y ds = \pi/h \int \sqrt{4h^2y^2 + a^4} \, dx = a\pi/h \int \sqrt{4hx + a^2} \, dx = a\pi(4hx + a^2)^{3/2}/6h^2$ (using formula (43), Art. 65, $n = 1$). Limits are $x = h$, $x = 0$.

Hence $S = \pi a[(4h^2 + a^2)^{3/2} - a^3]/6h^2$. *Ans.*

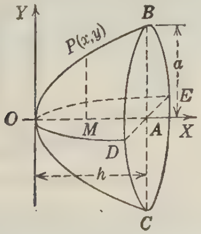

Fig. 201.

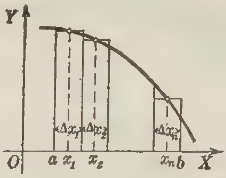

Fig. 202.

69. Integration as a summation

A definite integral is the limit of a sum of differential (infinitesimal) elements. Many useful applications of the integral calculus depend upon the fundamental theorem of integral calculus, which, stated abstractly, is to the following effect: Given a function $f(x)$ continuous in interval from $x = a$ to $x = b$. Let this interval (Fig. 202) be divided into any number (n) of parts of respective lengths Δx_1, Δx_2 . . ., Δx_n. On each of these segments (Fig. 202)

take a point, and let the values of x at these points be $x_1, x_2, \ldots, x_n$, respectively. Then the corresponding values of $f(x)$, are $f(x_1), f(x_2), \ldots, f(x_n)$. Form the sum of the products of each of these values of $f(x)$ by the length of the corresponding segment, namely the sum, $f(x_1)\Delta x_1 + f(x_2)\Delta x_2 + \ldots + f(x_n)\Delta x_n$. Let the number of segments be increased indefinitely so that the length of each approaches zero, then the limiting value of the above sum is the value of the integral of $f(x)dx$ evaluated for limits $x = a$, $x = b$. In the usual notation, $\int_a^b f(x)dx = \underset{n = \infty}{\text{Limit}} \ (f(x_1)\Delta x_1 + f(x_2)\Delta x_2 + \ldots + f(x_n)\Delta x_n)$.

Each term of the sum in the right-hand member is a DIFFERENTIAL ELEMENT. The value of the theorem lies in affording means of calculating the limit of a sum of differential elements of a certain form. The theorem has wide application.

In Fig. 202, the curve is $y = f(x)$; the products $f(x_1)\Delta x_1$, etc., are the areas of rectangles; the sum of the products is approximately the area under the curve, and the limit of the sum is the exact area. But this also equals the definite integral in the left-hand member in the above equation (Art. 68). Hence the result as above.

Examples. (1) The area swept over by the radius vector in Fig. 203 is the limit of the sum of the circular sectors with radii ρ_1, ρ_2, etc., and central angles $\Delta\theta_1$, $\Delta\theta_2$, etc., hence of area $\frac{1}{2}\rho_1{}^2\Delta\theta_1$, $\frac{1}{2}\rho_2{}^2\Delta\theta_2$, etc. (See Art. 29.) The fundamental theorem leads at once to the formula (Art. 68) $A = \frac{1}{2}\int \rho^2 d\theta$.

(2) The volume of the solid of revolution about OX (Fig. 204) may be considered the limit of the sum of circular cylinders with altitudes Δx_1, Δx_2, etc., and base radii y_1, y_2, etc., hence of volumes $\pi y_1{}^2\Delta x_1$, $\pi y_2{}^2\Delta x_2$, etc. The fundamental theorem gives immediately $V = \pi\int y^2 dx$.

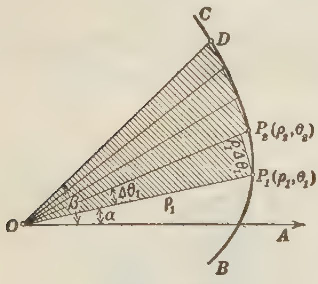

FIG. 203.

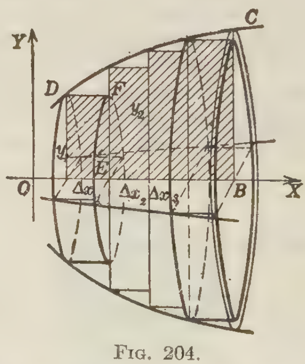

FIG. 204.

(3) A certain solid answers the following description: the base is an ellipse with semi-axes a, b (Art. 50); plane sections standing on the base and perpendicular to the major axis are squares. Find the volume.

With axes OX, OY in the base (Fig. 205), the equation of the ellipse is $b^2x^2 + a^2y^2 = a^2b^2$, or $y^2 = b^2(a^2 - x^2)/a^2$. Divide the solid into slices of equal infinitesimal thickness Δx by sections perpendicular to OX, and consider these slices trimmed into rectangular blocks such as $PQMN - P'Q'M'N'$. The co-ordinates of M are (x, y). The volume of this block $= 4y^2\Delta x$. Then the required volume is the limit of the sum of all such blocks when the thickness (Δx) approaches zero. Hence

$$V = \int 4y^2 dx = 4\int b^2(a^2 - x^2)/a^2 \cdot dx = 4b^2(a^2x - \tfrac{1}{3}x^3)/a^2,$$

substituting the value of y^2 from equation of base. The limits are $x = -a$, $x = a$, giving $V = 16ab^2/3$. *Ans.*

(4) **Work expended in friction in thrust bearings.** A vertical shaft M turns in a bearing (Fig. 206). At a distance x in. from the axis of the shaft let the normal pressure on the bearing due to load P lb. in the direction of the shaft axis be p lb. per sq. in. (unit normal pressure). Then the normal pressure on an infinitesimal ring of radius x and width dx is $p \times 2\pi x\, dx$ (since $2\pi x\, dx$ = the area of the ring). Then the load P must equal the sum of the normal pressures on all such infinitesimal rings, that is, $P = 2\pi \int px\, dx$. Let f = the coefficient of sliding friction. Then the work expended in one revolution in friction on an infinitesimal ring $= fp \times 2\pi x\, dx$ times the circumference of the ring $(2\pi x)$. Hence the total work expended, W, is the sum of the above elements of work for all such rings, that is $W = 4\pi^2 f \int px^2 dx$ in in.-lb. The relation between W and P is $W = 2\pi fP \int px^2 dx \div \int px\, dx$. For a collar bearing (Fig. 206) the limits are $x = \frac{1}{2}d$, $x = \frac{1}{2}D$. If p is everywhere constant (the usual assumption),

$$W = fP \times 4\pi(D^3 - d^3)/3(D^2 - d^2).$$

(5) **Center of gravity. Plane line.** Divide the line into infinitesimal parts of length ds, multiply each ds by its perpendicular distance r from a given axis in the plane of the line,

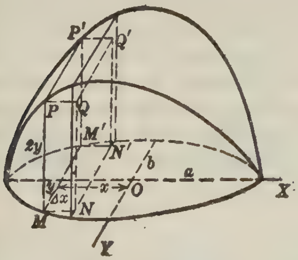

FIG. 205.

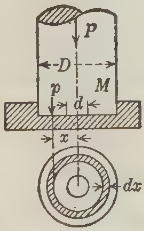

FIG. 206.

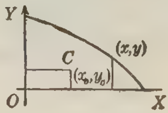

FIG. 207.

add all such products, which gives the STATIC MOMENT M of the line with respect to the axis, or $M = \int r\, ds$. Divide M by the length of the line and the result is the perpendicular distance of the center of gravity C from the given axis. A similar argument holds for plane areas, solids of revolution, etc. The formulas follow. Center of gravity is C.

Plane line. Let $C = (x_0, y_0)$; (x, y) any point on the line; L = length of line; $x_0 = \int x\, ds/L_1$, $y_0 = \int y\, ds/L_1$.

Plane area, bounded by a curve and the rectangular axes OX, OY (Fig. 207). $C = (x_0, y_0)$. A = area. (x, y) = any point on the boundary curve. $x_0 = \int xy\, dx/A$, $y_0 = \int xy\, dy/A$.

Solid of revolution. Let OX be the axis of revolution, V = volume, x_0 = distance of C from origin. The equation of the meridian section is $y = f(x)$. $x_0 = \pi \int xy^2 dx/V$.

(6) **Moment of inertia. Plane line.** The argument is the same as in Ex. 5 above, except that each infinitesimal length is multiplied by r^2. Hence the moment of inertia $I = \int r^2 ds$. In the following formulas, the subscript indicates the AXIS OF REFERENCE.

Plane line $I_x = \int y^2 ds$, $I_y = \int x^2 ds$; (x, y) = any point on line.

Plane areas as in Fig. 207. $I_x = \int y^2 x\, dy$, $I_y = \int x^2 y\, dx$; (x, y) = any point on boundary curve.

70. Approximate integration

Evaluation of $\int_a^b f(x)dx$. When a definite integral cannot be worked out by the tables available, an approximate value may be found by one of the following rules: (1) Expand $f(x)$ into a power series (Art. 62), integrate term by term, and evaluate the new series for the given limits.

(2) Plot the curve $y = f(x)$. The numerical measure of the area between the curve, the X-axis, and the ordinates at $x = a$ and $x = b$ is the value of the integral.

(*a*) Find this area by counting squares of cross-section paper.
(*b*) Use Simpson's Rule, Art. 29.
(*c*) Use a planimeter or integraph (MECHANICAL QUADRATURE). **(16)**

71. Derivation of formulas for given experimental data

To determine a formula (EMPIRICAL EQUATION) satisfied by given experimental data, when the law obtaining in the experiment is unknown, the data should be plotted on cross-section paper and the equation of a curve to "fit the points" derived. (Fig. 208.) The curve need not pass through all plotted points; derivation of an equation satisfied exactly by the given data is not the object, since such data are subject to errors of determination; a simple formula fulfilling the conditions with a degree of accuracy warranted by the data is the end desired.

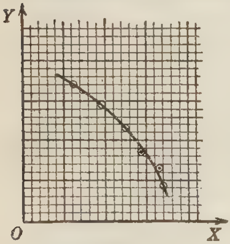

FIG. 208.

Acquaintance with several standard curves (Figs. 209–212) will assist in choosing the formula to be tested. Comparison of the curve suggested by the graph of the given data with these figures will suggest the law to be tried. Type laws are:

1. STRAIGHT-LINE LAW: $y = mx + b$.
2. POWER LAW: $y = ax^n$. (Figs. 209, 210.)
3. EXPONENTIAL LAW: $y = be^{ax}$. (Fig. 211.)
4. HYPERBOLIC LAWS: $y = (ax + b)/x$. (Fig. 216, I);
$y = x/(ax + b)$. (Fig. 216, II).

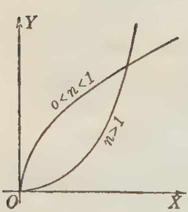

FIG. 209.

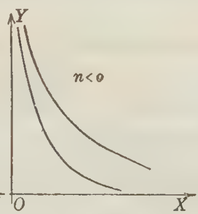

FIG. 210.

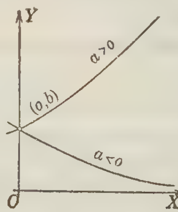

FIG. 211.

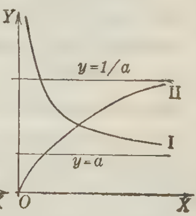

FIG. 212.

Test for a straight-line law may be made with a straight-edge; the test is affirmative when deviations from the straight line are small, some positive and some negative, and curve has no systematic curvature.

Constants in a straight-line formula may be determined by:

1. *Selected points.* Two points on the plot may be selected such that a straight line drawn through them gives satisfactory distribution of all points.

If the corresponding values selected are (x_1, y_1) and (x_2, y_2), solve the simultaneous equations $y_1 = mx_1 + b$ and $y_2 = mx_2 + b$, for the constants m and b, and place these values in the formula $y = mx + b$.

2. *Method of averages.* Substitute each pair of given values of x and y in the formula $y = mx + b$, thus forming the OBSERVATION EQUATIONS (equal in number to the number of determinations of x, y in the experiment); divide these observation equations into two groups as nearly equal in number as possible; add together all equations of each group to obtain one final equation for each group, and solve these final equations for m and b. Place the resulting values of m and b in the formula $y = mx + b$.

W	E	W	E
10	3¼	60	10½
20	4⅞	70	12¼
30	6¼	80	13¾
40	7½	90	15
50	9	100	16½
(150)	(30⅞)	(400)	(68)
	(Totals)		

Example. In an experiment with a pulley, the effort E lb. required to raise a load W lb. was found to be as in the accompanying table.

Solution. (Fig. 213.) **(1)** Straight line drawn through (30,6¼) and (100,16½) fits points well. Substituting these values in $y = mx + b$, equations are $6.25 = 30m + b$, $16.5 = 100m + b$. Solving, $m = 0.146$, $b = 1.86$. Hence the law is $E = 0.146W + 1.86$. *Ans.*

(2) Take first 5 observation equations, $3\frac{1}{4} = 10m + b, \ldots, 9 = 50m + b$, and add them; result is $30\frac{7}{8} = 150m + 5b$. Taking last 5, namely $10\frac{1}{2} = 60m + b, \ldots 16\frac{1}{2} = 100m + b$, and adding, $68 = 400m + 5b$. Solving, $m = 0.148$, $b = 1.72$. Hence result, $E = 0.148W + 1.72$. *Ans.*

3. *Method of least squares.* If the degree of accuracy of the experiment warrants, which is not often the case with engineering data, the method explained in Art. 22 may be used.

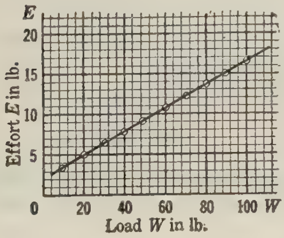

FIG. 213.

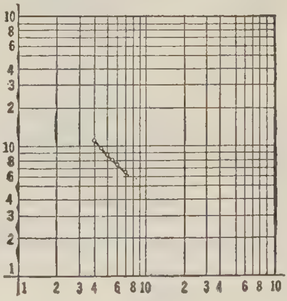

FIG. 214.

Test for power law $y = ax^n$. If the graph suggests a curve of the type in Fig. 209 or 210, the test to apply is to plot the points $(\log x, \log y)$. If a power law holds, a straight line will fit these points, because from $y = ax^n$, it follows that $\log y = \log a + n \log x$; or, putting $\log y = y'$, $\log a = a'$ and $\log x = x'$, the result is $y' = a' + nx'$, which is the equation of a straight line. The constants n and a' are found as described above; and a comes from $\log a = a'$. Values of a and n placed in $y = ax^n$ will give the desired equation.

Logarithmic cross-section paper is constructed by laying off logarithmic scales (Art. 5) on each of two perpendicular axes (Fig. 214) with the intersection marked 1 on both, and drawing lines through the points of division parallel to the axes. (Such paper, as well as semi-logarithmic paper (see below) can be purchased.) The experimental values, plotted to the scales shown in Fig. 214, are actually plotted as their logarithms with respect to ordinary

rectangular co-ordinate scales, and permit testing for a power law without looking up logarithms.

Example. Pressure (p = pounds per square inch) and volume (v = cubic feet) of 1 lb. of saturated steam were measured as in the adjoined table. Find a law for the data.

v	p
4	110
4.5	97.1
5	86.8
5.5	78.4
6	71.5
7	60.7

v'	p'	v'	p'
0.6021	2.0414	0.7404	1.8943
0.6532	1.9872	0.7782	1.8543
0.6990	1.9385	0.8451	1.7832
(1.9543)	(5.9671)	(2.3637)	(5.5318)

Solution. The curve suggested in Fig. 215 is of type in Fig. 210. A test on logarithmic cross-section paper, Fig. 214, shows that a power law, $p = av^n$ applies. To find the equation, tabulate values of $\log v = v'$ and $\log p = p'$, the relation being $p' = a' + nv'$ ($\log a = a'$), and apply the method of averages. Add the first three observation equations, and the last three (see table)

The results are, $5.9671 = 3a' + 1.9543n$ and $5.5318 = 3a' + 2.3637n$. Solving, $n = -1.063$, $a' = 0.6925$. $a = 480$. $p = 480v^{-1.063}$, or $pv^{1.063} = 480$. *Ans.*

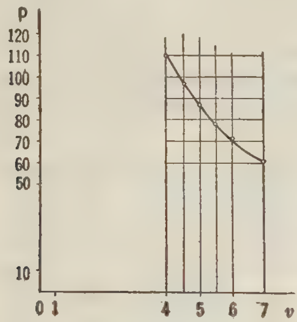

FIG. 215.

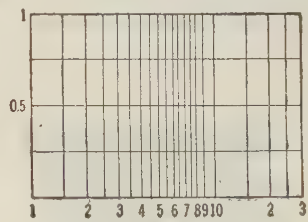

FIG. 216.

Test for exponential law $y = be^{ax}$. Type of curve, Fig. 211. Plot the experimental points as (x, $\log y$). If a straight line fits these points, an exponential law holds.

To verify this statement, take logarithms of both members of the equation, which gives $\log y = \log b + ax \log e$. Putting $\log y = y'$, $\log b = b'$, $a \log e = a'$, the result is $y' = b' + a'x$, which is the equation of a straight line.

Semi-logarithmic cross-section paper is constructed by laying off a logarithmic scale (Art. 5) from the origin on one axis of co-ordinates, and drawing lines through points of division parallel to the other axis. Draw equidistant lines parallel to the first axis. (Fig. 216.) Points (x, $\log y$) can be plotted quickly on such paper without determination of the actual logarithms and testing the data for an exponential law is thus expedited.

Test for hyperbolic laws. (See Fig. 212.) Equation $y = (ax + b)/x$ may be written $xy = ax + b$. Hence points (x, xy) lie on a straight line. Equation $y = x/(ax + b)$ is the same as $x/y = ax + b$, and therefore the points (x, x/y) lie on a straight line.

Other laws. The preceding five equations are simple "TWO-CONSTANT LAWS" and suffice for solution of many problems. Laws with three constants are:

(5) $y = a + bx + cx^2$ (PARABOLIC LAW),
(6) $\log y = a + bx + cx^2$,
(7) $y = ax^n + c$,
(8) $y = be^{ax} + c$.

When given values of x differ by a constant increment Δx (Art. 55), points $(x, \Delta y)$ will follow a straight-line law if (5) applies, and points $(x, \Delta \log y)$, if (6) holds. Curves for (7) and (8) differ from Figs. 209–210, and Fig. 211, respectively, only in the position of the X-axis. (Line $y - c = 0$ has the same relation to the curves as the X-axis in the figures named.) Value of c can often be found by trial and y replaced by $y - c$ in the methods explained above. (**16, 17, 18**.)

72. Charts for engineering formulas

The following material deals with methods of so treating formulas involving several variables that corresponding values of these variables can be read immediately from a chart. The methods possess wide application.

Notation. The variables are denoted by z, z_1, z_2, z_3, etc., and functions $f(z)$, $f(z_1)$, $F(z_1)$, $g(z_2)$, etc. of them by f, f_1, F_1, g_2, etc.

Function scales. The logarithmic scale (Art. 5) is a simple example of a function scale. In general, to construct a function scale for $f(z)$, lay off on a line a uniform scale of lengths with decimal subdivisions, calculate $f(z)$ for a number of values of z occurring in the given problem, lay off these values on the scale of lengths, and inscribe at each point thus located the corresponding value of z. If values of $f(z)$ are denoted by x, then $x = f(z)$ is called the equation of the function scale. In practice a SCALE FACTOR m (a constant) is introduced, *i.e.*, the equation of the scale is written $x = m\,f(z)$. The value of the scale factor in any given case is found as follows:

Example. Required a scale 10 in. long for $\log z$ when z varies from 0.01 to 100. *Solution.* Values of $\log z$ run from -2 to 2, a range of 4 units. Since $10/4 = 2.5$, the equation of the scale is $x = 2.5 \log z$. Generally, if the length of the scale is L in. and the range of values of the function is Z units, $m = L/Z$. Only a limited number of values of z appear on the scale; division marks indicate intermediate values. The subdivisions of the uniform scale of lengths may be retained when readings of values of $f(z)$ are desired. The function scales for $m\,f(z)$ and $m\,f(z) + c$ (c = a constant), are identical; the addition of a constant simply shifts the scale constructed for $m\,f(z)$ along the scale of lengths. If values of $f(z)$ are large, either a scale for $m\,f(z)$, where m is small, may be constructed; or a scale for $f(z) - c$, where c is large. The function scales thus far discussed, being laid off on a straight line, are called STRAIGHT SCALES.

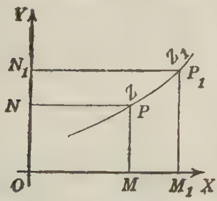

FIG. 217.

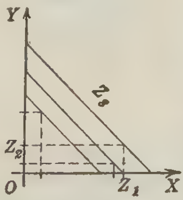

FIG. 218.

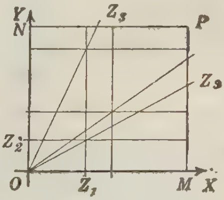

FIG. 219.

Curved scales. Let the straight scales $x = f(z)$ and $y = g(z)$ be constructed on perpendicular axes. Let M and N (Fig. 217) be points with the same value of z. Plot $x = OM$, $y = ON$. Again, let z have the same value z_1 at M_1, N_1. Plot P_1. Draw a smooth curve through all such points, and mark at each point corresponding values of z. The result is a CURVED SCALE. Equations $x = f(z)$, $y = g(z)$ are parametric equations of the curve. (Art. 45.) An indefinite number of curved scales may be constructed on any curve, corresponding to different parametric equations for that curve.

73. Charts with a network of lines

Three variables. From the explanation below it will appear that the object is to construct three systems of curves such that corresponding values of the variables are attached to three curves through a common point. In the examples given such a system of curves is composed of straight lines and easily constructed. In other cases the labor involved is so great that another type of chart is to be preferred. (See Art. 74.)

Type 1. $f_2 = f_1 + f_3$. On perpendicular axes OX, OY (Fig. 218) construct the scales $x = m_1 f_1$, $y = m_2 f_2$, and draw a net work of parallels to the axes through the points of division. Construct the system of parallel lines $y = m_2\, x/m_1 + m_2 f_3$ which result by assigning to z_3 the values used in the problem, and mark on each line the corresponding value of z_3, called the PARAMETER of the system. The values of z_1, z_2, z_3 attached to any three lines in the diagram through a point will satisfy the equation. From the given data it may be desirable to use the scales $x = m_1 f_1 + c_1$, $y = m_2 f_2 + c_2$. Parallel lines are now $y = m_2(x - c_1)/m_1 + m_2 f_3 + c_2$. In practice such constants are usually introduced. See Ex. 1 below.

Type 2. $f_2 = f_1 f_3$. Construct scales $x = m_1 f_1$, $y = m_2 f_2$ as in Type 1, and the system of lines $y = m_2 f_3 x/m_1$ intersecting at $O(x = 0,\ y = 0)$. (Fig. 219.) If MP and NP are drawn through the extremities of the scales on OX and OY, the values of z_3 may be conveniently written along these lines. If the scales $x = m_1 f_1 + c_1$, $y = m_2 f_2 + c_2$, are used, the system of lines is $y - c_2 = m_2 f_3\,(x - c_1)/m_1$, passing through (c_1, c_2). Transforming $f_2 = f_1 f_3$ by taking logarithms gives $\log f_2 = \log f_1 + \log f_3$, which is in the form of Type 1.

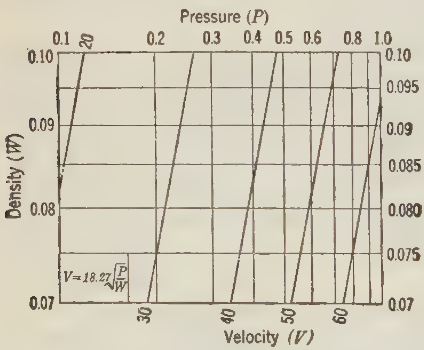

FIG. 220.

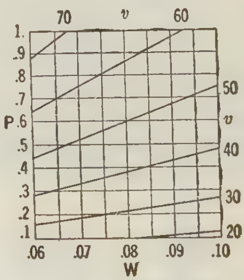

FIG. 221.

Example 1. Fig. 220 is a chart for $V = 18.27\sqrt{P/W}$, the formula for measurement of velocity of air by a Pitot tube. Taking logarithms and transposing, $\log W = \log P - 2 \log (V/18.27)$ which is Type 1. The scales used are $y = 25 \log 10W$, $x = 5 \log 10P$. The system of parallel lines is $y = 5x - 50 \log (V/18.27)$. Values of V are marked on the ends of the lines. This example illustrates logarithmic transformation of a given formula to bring it under Type 1.

Example 2. The preceding equation may be written $P = 0.003\ Wv^2$, and then comes under Type 2. Fig. 221 shows a chart, with scales $y = 5P$, $x = 100\ W$, and lines $y/x = 0.00015\ v^2$. Equations of the bounding vertical lines are $x = 6$, $x = 10$; of the bounding horizontal lines, $y = 0.5$, $y = 5$. Uniform scales are laid off on these lines. The system of lines for v may be plotted by calculating the points of intersection with the bounding lines, or also, by drawing lines through $x = 0$, $y = 0$, which is in this case a point off of the chart.

Four variables. Extensions of the preceding methods are shown in Figs. 222–224.

Type 3. $f_1 + f_2 = f_3 + f_4$. (Fig. 222.) Construct the function scales $x = m_1 f_1 + c_1$ on OM, $x' = m_3 f_3 + c_3$ on PQ, and two systems of parallel lines, (1) $y = m(x - c_1)/m_1 + mf_2$, with parameter z_2 (AB, etc.); (2) $y = m(x' - c_3)/m_3 + mf_4$, with parameter z_4 (CD, etc.). Corresponding values of z_1, z_2, z_3, z_4 are determined as indicated in the figure.

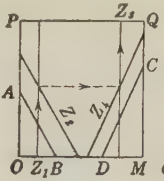

Fig. 222.

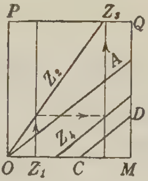

Fig. 223.

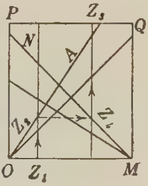

Fig. 224.

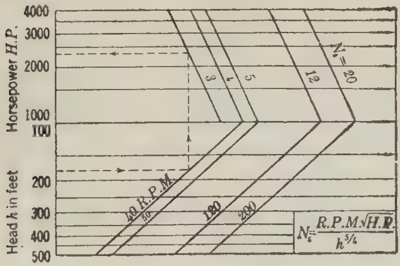

Fig. 225.

Type 4. $f_1 f_2 = f_3 + f_4$. (Fig. 223.) Construct function scales $x = m_1 f_1 + c_1$ on OM, $x' = m_3 f_3 + c_3$ on PQ, and two systems of lines, (1) $y = mf_2\,(x - c_1)/m_1$, with parameter z_2 (lines through $O(c_1, 0)$, OA, etc.), (2) $y = m(x' - c_3)/m_3 + mf_4$, with parameter z_4 (parallel lines CD, etc.). Corresponding values of z_1, z_2, z_3, z_4 are indicated in the figure.

Type 5. $f_1 f_2 = f_3 f_4$. (Fig. 224.) Construct function scales $x = m_1 f_1 + c_1$ on OM, $x' = m_3 f_3 + a$ on PQ, ($OM = a$), and two systems of lines; (1) $y = mf_2\,(x - c_1)/m_1$, with parameter z_2 (lines through $O(c_1,\ 0)$), and (2) $y = mf_4(x' - a)/m_3$, with parameter z_4 (lines through M). Corresponding values of z_1, z_2, z_3, z_4 appear in the figure.

Example 1. Fig. 225 shows a portion of a chart for $N_S = \text{R.P.M.}\sqrt{\text{H.P.}}/h^{5/4}$, which is the formula for the specific speed (N_S) for impulse and reaction water wheels. Taking logarithms, $\log N_S - \frac{1}{2}\log \text{H.P.} = \log \text{R.P.M.} - 5/4 \log h$. This comes under Type 3. The scales are $y = 3.3 \log 0.001$ H.P., $y' = -3.3 \log 0.01\, h$, both of which are laid off on the line $x = 3 \log 3$. The systems of parallel lines are $4.4\,x - 5\,y' = 13.2 \log 0.3$ R.P.M., $2.2x + y = 6.6 \log 3\,N_S$. The Y-axis is off the chart. For lines of the two systems intersecting on the X-axis (horizontal line in figure through $h = 100$), R.P.M. $= 10\,N_S$.

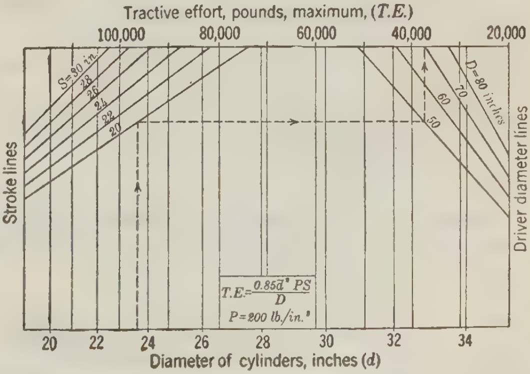

Fig. 226.

Example 2. Fig. 226 shows the lower part of a chart for T.E. $= 0.85\, d^2\, PS/D$, which is the formula for the tractive effort of a simple two-cylinder locomotive, with boiler pressure $P = 200$ lb./in.² The formula may be written $170\, d^2\, S = \text{T.E.} \times D$, and comes

under Type 5. The scales are $x = 0.0085\ d^2$, $x' = 12 - 0.75\ T/10{,}000$, both laid off on horizontal lines. The two systems of lines are (1) $y = Sx/30$, (2) $y = D(12 - x')/45$.

74. Alignment charts

Principle. For many formulas in engineering it is possible to construct function scales in such a way that readings on them at points on one or more lines will satisfy the formula. Many of these charts are simple and easily constructed. Alignment charts for the types in Art. 73 are given below.

Type 6. $f_1 + f_2 = f$. (Fig. 227.) Scales for m_1f_1, m_2f_2, mf are constructed on parallel axes with the conditions $m_1/m_2 = a/b$, $m = m_1m_2/(m_1 + m_2)$, and adjusted so that readings at M_1, M, M_2, will satisfy the equation. Then readings at any three points P_1, P, P_2, in line, will also satisfy the formula.

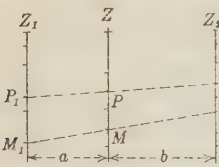

FIG. 227.

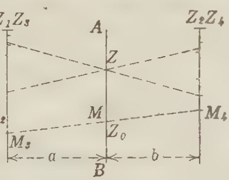

FIG. 228.

Type 7. $f_1 + f_2 = f_3 + f_4$. (Fig. 228.) Scales for m_1f_1, m_3f_3 are constructed on one axis and, scales for m_2f_2, m_4f_4, on a parallel axis, with $m_1 = m_3$, $m_2 = m_4$. A third axis AB is then drawn so that $m_1/m_2 = a/b$. Set $f_1 + f_2 = z$, and $f_3 + f_4 = z$. Chart the first of these equations as in Type 6, and compute z $(= z_0)$ at some point as M. No scale for z on AB need be constructed. Chart the second equation, adjusting the scales for m_3f_3, m_4f_4 so that readings at M_3, $M(z_0)$, M_4 on a line $M_3M\ M_4$ will correspond. If any two lines intersect on AB, readings for z_1, z_2, on one line, and z_3, z_4, on the other line, will satisfy the equation.

Example. Fig. 229 is a chart for $N_c = 1{,}550{,}000\ d^2/W^{1/2}l^{3/2}$, which is a formula for the determination of the critical speed of a shaft when the load is concentrated midway between the bearings. Taking logarithms, $\log N_c + \frac{1}{2}\log W - \log 1{,}550{,}000 = 2\log d - \frac{3}{2}\log l$, which is the form of Type 7. Scales are laid off for $10 \log d$, and $3.75 \log l$ with $m_3/m_4 = -2$, hence with axis AB to the right. The line through $d = 1$, $l = 1$ cuts AB in $z = 0$. For N_c, the scale is $5 \log N_c$. The line joining $N_c = 15{,}500$ and $z = 0$ must cut the W-scale at $W = 10{,}000$. The scale for W is $-1.25 \log W$.

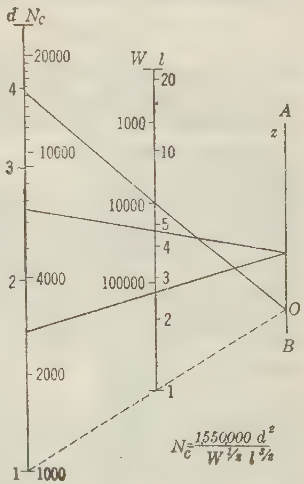

FIG. 229.

Type 8. $f = f_1/f_2$. (Fig. 230.) Construct scales for m_1f_1, $-m_2f_2$ on parallel axes, and adjust these so that line AB drawn from $A(f_1 = 0)$ to $B(f_2 = 0)$ makes a convenient angle with AM (usually 45°). On AM construct a scale for $x = am_1f/(m_2 + m_1f)$. Project these graduations on to AB by lines parallel to the axes, and mark at these points on AB the same values for z as on AM. Values of z_1, z, z_2 on any transversal will satisfy the equation. This type is called a Z-chart.

Type 9. $f_1/f_2 = f_3/f_4$. (Fig. 231.) Construct scales for m_1f_1, $-m_2f_2$, m_3f_3, $-m_4f_4$, with $m_1/m_2 = m_3/m_4$, on axes as indicated, with $f_1 = f_3 = 0$ at

A, $f_2 = f_4 = 0$ at B. Transversals intersecting on diagonal AB will cut the scales in corresponding values of z_1, z_2, z_3, z_4.

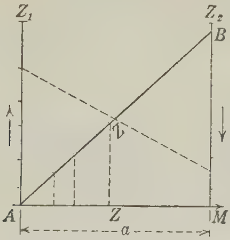

FIG. 230.

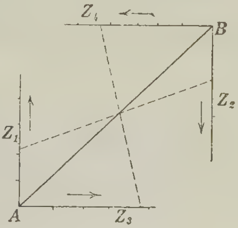

FIG. 231.

Type 10. $f_1 + f_2 = f_3/f_4$. (Fig. 232.) Lay off scales for m_1f_1, m_3f_3, on AM starting at A ($f_1 = f_3 = 0$), scale for m_4f_4 on AB from A ($f_4 = 0$), scale downward for m_2f_2 from B ($f_2 = 0$) on BQ, with $m_1 = m_2$, and m_3, $m_4 = m_1/AB$. Parallel index lines will cut the scales in corresponding values of the variables, z_3, z_4, on one line, and z_1, z_2, on the other.

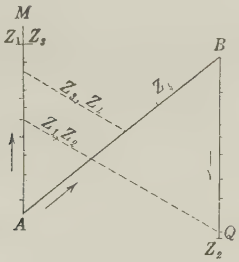

FIG. 232.

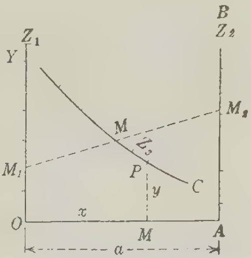

FIG. 233.

Type 11. $f_1 + f_2f_3 = F_3$. (Fig. 233.) This type brings in a curved scale. (Art. 72.) Construct the scales $y_1 = OM_1 = m_1f_1 + c_1$, $y_2 = AM_2 = m_2f_2 + c_2$, and the curved scale $x = OM = am_1f_3/(m_2 + m_1f_3)$, $y = MP = (m_1m_2F_3 + m_2c_1 + m_1c_2f_3)/(m_2 + m_1f_3)$, on the curve C. Readings on any transversal $M_1M\ M_2$ will satisfy the equation.

For other types, some of which are extensions of the preceding, see (**16, 17, 18, 19**).

MATHEMATICAL TABLES

75. Explanation of tables

Table 1. Squares of numbers with three significant figures from 1.00 to 9.99 are tabulated. Corrections to be *added* for a fourth figure 1, 2, 3, 4, 5 are given in right-hand columns. For a fourth figure 6, 7, 8, 9, take the

tabular entry for the next larger number of three figures and *subtract* the correction given for 4, 3, 2, 1, respectively.

Examples. $(1.285)^2 = 1.638 + .013 = 1.651$. $(1.286)^2 = 1.664 - .010 = 1.654$.

If the decimal point is moved *one* place in N, move it *two* places in the tabular number.

$$(0.128)^2 = 0.01638. \quad (12.85)^2 = 165.1.$$

Table 2. Cubes of numbers. Method of correction for a fourth significant figure is the same as above. Interpolate for a fourth significant figure when corrections in the right-hand column are missing. If the decimal point is moved *one* place in N, move it *three* places in the tabular number.

$$(9.86)^3 = 958.6. \quad (0.986)^3 = 0.9586. \quad (98.6)^3 = 958600.$$

Table 3. Square roots. If the decimal point is moved two places in N, move it one place in the tabular number.

$$\sqrt{3.142} = 1.773. \quad \sqrt{314.2} = 17.72. \quad \sqrt{0.03142} = 0.1773.$$

Table 4. Cube roots. If the decimal point is moved *three* places in N, move it one place in the tabular number.

$$\sqrt[3]{34.98} = 3.270. \quad \sqrt[3]{34980} = 32.70. \quad \sqrt[3]{0.03498} = 0.3270.$$

Table 5. Reciprocals. The tabular values *decrease* with *increasing* N, hence the correction given in the right-hand column for a fourth figure 1, 2, 3, 4, 5 must be *subtracted* from the tabular value given for the first three figures of N. For a fourth figure 6, 7, 8, 9, *add* to the tabular value given for the next larger number the correction for 4, 3, 2, 1, respectively.

$$1 \div 3.654 = 0.2736. \quad 1 \div 3.658 = 0.2734.$$

If the decimal place in N is moved to *right* (or *left*), move it the same number of places to *left* (or *right*) in the tabular value.

$$1 \div 0.3654 = 2.736. \quad 1 \div 0.003654 = 273.6.$$

Tables 6–8. Circumferences and areas of circles; volumes of spheres. Formulas for calculation are $Circumference = \pi D$, $Area = \pi D^2/4$, $Volume = \pi D^3/6$, $D = diameter$, $\pi = 3.141593$. In Tables 6–8, move the decimal point one place in **circumference,** two places in **area,** three places in **volume,** if the decimal point is moved one place in D. If the circumference C, area A, or volume V is given, diameter D is found by

$$D = 0.31831C = 1.12838\sqrt{A} = 1.24070\sqrt[3]{V}.$$

Table 9. Circular segments. (Art. 29, Fig. 97.) To find the height or chord for any radius, multiply the corresponding tabular number by the radius. To find the area, multiply the tabular number by the square of the radius.

Given a central angle 36° and radius 2, then height $= 0.0489 \times 2 = 0.0978$, chord $= 0.6180 \times 2 = 1.2360$, area $= 0.02027 \times 4 = 0.0811$.

Tables 10–19 are self-explanatory.

Table 20. Exponentials. Values of e^u and e^{-u}. For definition of e, see Art. 15. Interpolation will be inaccurate for values of u greater than 1. The last column gives the common log of e^u or multiples of $\log_{10} e = 0.434294$. Interpolation should not be used in this column.

Table 21. Hyperbolic functions are expressions of frequent occurrence involving e^u. Those tabulated are the hyperbolic sine ($\sinh u$), hyperbolic cosine ($\cosh u$), hyperbolic tanh ($\tanh u$), defined in terms of e^u as follows: $\sinh u = \frac{1}{2}(e^u - e^{-u})$, $\cosh u = \frac{1}{2}(e^u + e^{-u})$, $\tanh u = \sinh u/\cosh u$. Other hyperbolic functions are $\operatorname{sech} u = 1/\cosh u$, $\operatorname{cosech} u = 1/\sinh u$, $\coth u = 1/\tanh u$. Other relations between hyperbolic functions are $\cosh^2 u - \sinh^2 u = 1$, $\operatorname{sech}^2 u = 1 - \tanh^2 u$. Avoid interpolation for $u > 1$

Trigonometric and hyperbolic functions satisfy the equations $\sin ui = i \sinh u$, $\cos ui = \cosh u$, $(i = \sqrt{-1})$, see Art 21.)

Bibliography. (1) A good presentation of computation, errors, etc., is given by Langley, *A treatise on computation* (Longmans). (2) A short list follows. Wentworth-Smith, *Trigonometric and logarithmic tables, five places* (Ginn and Co.); *Macmillan's Logarithmic and trigonometric tables, five places* (Macmillan Co.); Wells, *New six-place logarithmic tables* (Heath and Co.); Hutton, *Mathmetical tables, seven places* (London); Schrön, *Seven-place tables* (German) (Brunswick). (3) A good explanation of the slide rule with numerous problems s given by Dunlop and Jackson, *Slide-rule notes* (Longmans). See also pamphlets published by the manufacturers, for example, Cox, *The Mannheim slide rule* (Keuffel and Esser Co.). Many other types of slide rules are on the market, some of which are designed for the solution of special problems. For illustrations and descriptions of these as well as a great variety of calculating machines see *Methods of calculation, a handbook of the Exhibition at the Napier Tercentenary Celebration* (G Bell and Sons, London). * The Standard Oil Co. has adopted the tierce, 42 gal., as its barrel, and this practice has been followed by other oil producers and refiners.

† British Imperial gallon = 1.20091 U. S. gal.

Capacity metric. The liter (l.) is the unit and the equivalent of the volume occupied by the mass of 1 kilogram of pure water at maximum density. The smaller units usually employed are the cubic centimeter (cu. cm. or cc.) and the cubic millimeter (cu. mm. or mm.^{3}) which are, for all practical purposes, 0.001 and 0.000001 liter respectively.

Table 39. Equivalent forces or weights per unit of volume

SECTION 25

PHYSICS

BY

FREDERICK E. BEACH

ASSOCIATE PROFESSOR OF PHYSICS, YALE UNIVERSITY, NEW HAVEN, CONN.

1. Density

The density of a substance is the mass per unit volume. When c.g.s. units are employed, the density becomes the SPECIFIC GRAVITY and is, for all practical purposes, the weight in grams per cubic centimeter. For densities of various common substances see Table 1.

Determination of density. For LIQUID, weigh a known volume. For SOLIDS in masses, weigh in air and in a liquid in which they sink and are insoluble. The loss in weight divided by the density of the liquid gives the volume of liquid displaced and hence the volume of the solid. For pulverized solids see Sec. 22, Art. 23.

Hydrometer is a weighted scale which floats in the liquid to be tested, and is weighted in such a way that the depth to which it sinks is proportional to the density of the liquid. Hydrometers are calibrated so that the scale reading cut by the liquid surface is the density of the liquid in the units chosen. Ordinarily specific gravity is read directly, but in some arts the Twaddell scale and in others the Baumé is used. For specific gravity greater than unity: Density = 1 + Twaddell degrees/200. Density at 15° C. = 144.3/(144.3 − Baumé degrees). For specific gravity less than unity; Density = 140/(130 − Baumé degrees).

2. Viscosity

A body that yields continually to forces tending to change its form is called viscous. The rate of shear in a fluid is directly proportional to the shearing stress and inversely to a property of the fluid of the nature of resistance or internal friction which is called the COEFFICIENT OF VISCOSITY.

FIG. 1.

Suppose the space between two parallel plates of area A (Fig. 1), and spacing d filled with an adherent fluid. Suppose the force F applied tangentially to one of the plates causes it to slide parallel to the other a distance l in the time t. Then $l/td = v/d$ is the rate of shear where $v = l/t$. The

coefficient of viscosity η is given by the equation $v/d = F/\eta A$. The unit of η is, accordingly 1 gm./1 cm. $\times$ 1 sec. The slowness of the motion v is commonly spoken of as the VISCOSITY of the system. The viscosity of a liquid may be found from the flow through a capillary tube. Let V be the volume which flows in a time, t, L the length of the tube, r its radius and p the pressure due to the head of the liquid, then $\eta = \pi p r^4 t/8LV$.

Table 1. Densities in grams per cc. (For metals, see Sec. 2, Table 1; for minerals, see Sec. 28, Table 2)

Temperature. The coefficient of viscosity decreases rapidly with rising temperature. (See Table 2.)

Relative viscosity or SPECIFIC VISCOSITY is the ratio of the viscosity of the fluid under consideration to that of water at the same temperature.

The apparatus employed for determination varies according to the viscosity of the liquid under investigation. For relatively viscous liquids, some form of the Engler viscosimeter is ordinarily employed; for relatively mobile liquids, the Ostwald apparatus is used.

Table 2. Viscosities

Substance	Temperature, degrees C.	η, $\frac{\text{gm.}}{\text{cm. sec.}}$
Water	0	0.0179
Water	20	0.0101
Water	40	0.00657

Machine oil	19	1.0
Paraffin oil	19	0.02
Sulphuric acid	20	0.22

Engler viscosimeter (Fig. 2), consists of a cup (A), fitted with a pipe orifice (C), a container (B) with a stirring mechanism (E, D), and a graduated flask (G). The cup (A) is provided with an air-insulated cover (c) and a pointed wooden stopper (b).

Take a sample approximately 15 per cent. greater in bulk than required to fill cup (A) to the top of the gage points. Strain the sample through a 100-mesh wire screen to remove foreign matter. Clean cup (A) with solvents such as benzol or alcohol; take particular care that the discharge orifice is thoroughly clean and dry. Soft tissue paper or filter paper is best for cleaning. Assemble the apparatus; place the pointed wooden stopper in the orifice; fill the inner cup to the top of the gage points; place cover (c) in position and insert thermometer (F). Fill chamber (B) with an oil of high boiling point, usually a heavy lubricating oil, and heat slowly, stirring the heating liquid, until the desired temperature is reached. Hold at this temperature until the liquid in cup (A) has reached the same temperature. Place container (G) so that the liquid will flow down the side of the container and thus prevent froth formation. Lift the pointed wood stopper and determine with a stop watch the elapsed time in filling the flask to the graduation mark. Repeat until concordant results are obtained. The time required to discharge an equal volume of distilled water under the same conditions of temperature and head on the discharge orifice should now be determined, after cleaning thoroughly. The ratio of the time of outflow of the oil to that of the water is the specific viscosity of the oil, referred to water at the same temperature, and is called the "Engler degree."

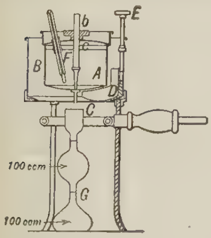

FIG. 2. Engler viscosimeter

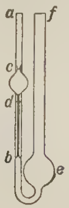

FIG. 3. Ostwald viscosimeter

Ostwald viscosimeter, used for mobile liquids is shown in Fig. 3. It consists of a fine capillary tube (db) about 10 cm. long and 0.4 mm. bore, connected at the upper end to a bulb containing a definite volume between the graduation marks (c) and (d).

Table 3. Relative viscosities of aqueous solutions compared to water

Normal solutions	Temperature, degrees C.	Relative viscosity
Ammonia	25	1.02
Ammonium chloride	17.6	0.98
Calcium chloride	20	1.31
Hydrochloric acid	25	1.07
Potassium chloride	17.6	0.98
Sodium hydrate	25	1.24
Sulphuric acid	25	1.09

The capillary is connected at the lower end by a U-tube to a large bulb (e), which in turn is connected to a tube of convenient size for filling.

The apparatus should be cleaned first with suitable oil solvents such as benzol, acetone, ether, or alcohol and then with warm chromic acid solution, and finally with water, then dried thoroughly by a current of air. Introduce into the leg (f) by means of a calibrated pipette, a definite volume of liquid sufficient to cause the bulb (e) to stand two-thirds full. Heat in a constant-temperature bath from 30 minutes to 1 hour. Next place a rubber tube at (a) and suck oil into this limb to some point above the mark (c). Remove the tube and allow the oil to flow down through the capillary (db) by gravity, taking the elapsed time by stop watch for the meniscus to pass from graduation (c) to graduation (d). Repeat until concordant results are obtained. A variation in elapsed time of 0.1 to 0.5 per cent. is allowable. Repeat with water at the same temperature, using the same volume of water as of oil. The ratio of time of flow of oil multiplied by the specific gravity of the oil, to the time of flow of the water multiplied by the specific gravity of the water gives the specific viscosity of the oil compared with water at the given temperature.

3. Radiation

The energy radiated from a black body depends both in quantity and quality (wave length), upon the temperature.

Table 4. Relative heat-radiating and reflecting powers

	Radiating	Reflecting
Lamp black	100	...
Writing paper	98	2
Ivory, marble	93 to 98	7 to 2
Glass	90	10
Ice	85	15
Gum lac	72	28
Cast iron, polished	25	75
Mercury	23	77
Wrought iron, polished	23	77
Zinc, polished	19	81
Steel, polished	17	83
Platinum, polished	24	76
Tin	15	85
Cast brass, dead polish	11	89
Cast brass, bright polish	7	93
Copper hammered	7	93
Gold plate	5	95
Silver, polished	3	97

Stephan's law. If Q is the quantity of energy in ergs radiated from an area A of a black body in a time t, the rate of loss $R = Q/At$ is $R = KT^4$ where K is a constant having the value 5.3 ergs/cm². sec. (deg.)^4, and T the absolute temperature in degrees C. The radiation from a black body at the temperature T_1 to one at the temperature T_2 will accordingly be $R = K(T_1^4 - T_2^4)$.

The rate at which a hotter body radiates heat and a colder body absorbs heat depends upon the state of the surfaces as well as the temperature. Surfaces that reflect well absorb little and *vice versa*, but radiating power and absorbing power are identical. Consequently radiation and absorption increase with the blackness and roughness of the surface but diminish with the smoothness, polish and whiteness of the surface. It is not possible in the present state of science to give more than relative values for the radiating and reflecting power of surfaces under similar conditions. See Table 4.

Table 5. Heat radiation, B.t.u. per hour per square foot of surface for 1° F. difference of temperature

Copper, polished	.0327
Tin, polished	.0440
Zinc or brass, polished	.0491
Tinned iron, polished	.0858
Sheet iron, polished	.0920
Sheet lead	.1329
Sheet iron	.5662
Glass	.5948
Cast iron	.6480
Iron, rusted	.6868
Wood, stone, brick	.7358

When a surface is not more than 30° F. hotter than the air into which it is radiating and the air is in the vicinity of 50° or 60° F., the rate of radiation may be taken as approximately proportional to the difference in temperature. Newton's law of cooling may be applied thus $Q/At = B(T_1 - T_2)$.

To convert to calories per square centimeter per second for a difference of 1° C. multiply by 1.356 $(10)^{-4}$.

4. Thermometry

Difference of temperature is commonly measured by change in volume of some selected substance, usually mercury in a glass tube.

Fahrenheit scale. The temperature of melting ice is marked 32° F. and that of steam from water boiling under normal atmospheric pressure (76 cm., or 29.92 in. of mercury), is marked 212° F.

Centigrade scale. On this scale the temperatures of the melting and boiling points are called respectively 0° C. and 100° C.

If T_F is a temperature read on a Fahrenheit thermometer and T_C the same temperature on a Centigrade thermometer one reading can be converted into the other by the equation $T_C = 5/9 \times (T_F - 32)$. See also Table 6.

Table 6. Conversion of thermometer readings

	70.0°	=	158.0°
Diff.	3.0	=	5.4
Diff.	0.4	=	0.7
	73.4°	=	164.1°

5. Calorimetry

DEFINITIONS. The quantity of heat required to raise the temperature of 1 gram of water 1° C. is called the CALORIE. As this amount varies slightly with temperature, it is usual to take the average value between 0° and 100° C., which is called the MEAN CALORIE. The quantity of heat required to raise a pound of water 1° F. is called the BRITISH THERMAL UNIT or B.T.U.

THERMAL CAPACITY (c), or water equivalent of a body, is the amount of heat required to raise the temperature of the body one degree. Thus the quantity of heat Q necessary to produce a change of temperature $t_1 - t_2$ in a body whose thermal capacity is c will be $Q = c(t_1 - t_2)$. SPECIFIC HEAT (S) of a substance is the thermal capacity per unit mass. This is numerically the ratio of the quantity of heat required to raise a given mass of the substance one degree to the quantity of heat required to raise an equal mass of water one degree. The quantity of heat Q necessary to produce a change of temperature $(t_1 - t_2)$ in a body whose mass is m and whose specific heat is s is $Q = ms(t_1 - t_2)$. The quantity of heat required to convert a gram of substance from the solid to the liquid state, without change of temperature, is called the LATENT HEAT OF FUSION. The quantity of heat Q necessary to melt m grams of a substance whose latent heat of fusion is L_F is $Q = mL_F$. A similar expression obtains for the change from the liquid to the vapor state and $Q' = m'\ L_V$ where L_V is the LATENT HEAT OF VAPORIZATION. See Table 7.

6. Coefficient of expansion

The fractional increase of a length at zero degrees for a rise of temperature of one degree is called the COEFFICIENT OF LINEAR EXPANSION. If L_t is the length at t degrees, L_0 the length at zero and λ the coefficient of linear expansion, $L_t = L_0(1 + \lambda t)$. For solids the relation $L_{t'} = L_t[1 + \lambda(t' - t)]$ is sufficiently exact. The COEFFICIENT OF CUBICAL EXPANSION is defined by $V_t = V_0(1 + \alpha t)$. For solids the cubical coefficient $\alpha = 3\lambda$. See Table 7.

Cubical expansion of liquids. The volume of a liquid may be exactly expressed as a function of the temperature by the relation: $V_t = V_0(1 + \alpha t + \beta t^2 + \gamma t^3)$. Values of these coefficients are given in the Smithsonian Tables. If, however, the temperature interval is not large, the relation $V_t = V_0(1 + \alpha t)$ may be used. Values of α in Table 8 are mean values for the vicinity of 18° C.

Coefficient of cubical expansion of gases at constant pressure of 76 cm. of mercury, has the practically uniform value of $\alpha = 1/273 = .00367$ per deg. C. WATER VAPOR between 0° and 162° C. has the mean value $\alpha = 0.004189$ per deg. C.

7. Thermal conductivity

The quantity of heat Q that is conducted across a slab of any substance having a facial area A, a thickness d and a difference of temperature $T_1 - T_2$ in a time t is given by the relation $Q = kA(T_1 - T_2)t/d$ where k is a constant defining a property of the material called THERMAL CONDUCTIVITY. See Table 7.

8. Humidity

ABSOLUTE HUMIDITY is the mass of water vapor per cc., *i.e.*, the density of the water vapor actually present. RELATIVE HUMIDITY is the ratio of the amount of water actually present to the amount necessary to saturate the air, the temperature remaining unchanged. The DEW POINT is the temperature at which the aqueous vapor begins to condense.

Table 7. Thermal properties of various substances. (For metals, see Sec. 2, Table 1)

Note—The specific heat is a mean value between 0° C. and 100° C. unless otherwise stated. The boiling points are for 76 cm. of mercury pressure. The specific heats of gases are for constant pressure of 76 cm.

§ The specific heat of water varies from 1.00 by only a few parts in a thousand. See Kaye and Laby, *Physical Constants*, page 56.

¶ This alloy, called Invar, has the smallest known coefficient of expansion. An alloy of 42% nickel with iron is called Platinite and has the same coefficient as glass. It is used for incandescent lamp bulbs and armored glass.

Absolute humidity at any temperature, t, may be found from the density of the water vapor, D, at the dew point t_d by the equation

$$\text{A. H.} = D \times \frac{273 + t_d}{273 + t}.$$

Relative humidity may be calculated from the definition or from the ratio

of the vapor pressure at the actual temperature to the vapor pressure at the dew point: R. H. = p_d/p_t.

Table 8. Values of α in the approximate equation for cubical expansion of liquids

Liquid	$\alpha \times 10^5$	Liquid	$\alpha \times 10^5$
Acetic acid	107	Turpentine	94
Alcohol, ethyl	110	Water, see special table	
Benzene	124	Mercury	18.15
Carbon disulphide	121	Solution, 1.6 per cent. NaCl in water	106
Chloroform	126	Solution, 26 per cent. NaCl in water	43.6
Ether, ethyl	163	Sulphuric acid, 100 per cent	57
Glycerine	53	Solution H_2SO_4, 50 per cent., in water	80
Olive oil	70		
Paraffine oil	90		
Petroleum, d = .847	104		

Table 9. Specific volume of water

Temp., deg. C.	Cc. per gm.	Temp., deg. C.	Cc. per gm.
0	1.00013	60	1.01705
4	1.00000	70	1.02270
10	1.00027	80	1.02890
20	1.00177	90	1.03590
30	1.00435	100	1.04343
40	1.00782	110	1.0515
50	1.01207	120	1.0601

Table 10. Freezing mixtures

Parts by weight	Temperature
1 NH_4NO_3 to 1 water	− 15° C.
8 $NaSO_4$ to 5 water	− 17
2 snow to 1 NaCl	− 18
3 snow to 4 $CaCl_2$ crystals	− 48

Example. Given the temperature of the air t = 14.5° C. and the dew point t_d = 9.2° C., required the absolute and the relative humidity.

From Table 11, by transformation of units, density of water vapor in saturated air is $D_{9.2}$ = 8.94 gm. per cu. met., whence A. H. $= 8.94 \cdot \frac{273 + 9.2}{273 + 14.5} = 8.78 \frac{\text{gm.}}{\text{cu. m.}}$.

Again from Table 11, the density for saturation at 14.5° is $D_{14.5}$ = 12.44 gm. per cu. m. whence R. H. $= \frac{\text{A. H.}}{D_{14.5}} = \frac{8.78}{12.44} = 0.706$.

By the tables $p_{9.2}$ = 8.66 mm. Hg and $p_{14.5}$ = 12.22 mm. Hg, hence

$$\text{R. H.} = 8.66/12.22 = 0.708.$$

9. Optics

Image. When light waves proceeding from a point are so modified that they either proceed from another point or appear to proceed from another point, the second point is called the image of the first. In the first case the image is REAL and the second VIRTUAL. In every case the condition of distinct vision is that the light shall proceed definitely from a point, or in other words that the wave front which enters the eye shall be accurately spherical.

Principal focus. When flat wave fronts, that is to say light from a very distant source, fall on a positive lens they are converged to a point (F), (Fig. 4, a), called the PRINCIPAL FOCUS; its distance from the center of the lens is called the focal length of the lens.

Real image. When the light proceeds from a point (O), (Fig. 4, b), farther from the lens than the focal distance, the waves after passing through the lens converge to a point (I)

(a) (b) (c)

FIG. 4.

between the principal focus and infinity. Thus a real image of (O) is formed at (I) and the ratio of the size of the image to the size of the object is the same as the ratio of their respective distances from the lens. Such real images are formed by a photographic lens and by the objective lens of a microscope or a telescope.

Virtual Image. When light proceeds from a point nearer the lens than the focal distance the waves after passing the lens appear to come from a point (I), (Fig. 4, c), behind the object (O), forming a virtual image at (I). The ratio of the size of the object and image is, as before, the same as the ratio of their distances from the lens. This is the way a lens is used as a magnifying glass. For distinct vision (CI) should be about 25 cm. (10 in.), which is taken as the conventional distance of reference. The magnification in this case is approximately 25 cm./(F) cm. since the object is near the principal focus.

Aberrations. Light-wave fronts, after modification by a lens, are (1) neither truly spherical, (2) nor the same for points on the axis and off the axis, (3) nor the same for different colored lights. The assemblage of points in the object is accordingly only imperfectly reproduced in the image formed by a simple lens. Defects (1) and (2) are called spherical aberrations. A sharp point in the object consequently appears hazy and elongated in the image, a plane does not appear flat and the relation of points in it is distorted. Defect (3) is called chromatic aberration and gives rise to overlapping colored images. Spherical aberration may be corrected by using two or more somewhat separated lenses, as in the familiar eyepiece of microscopes and telescopes. A compound lens that has been corrected for spherical aberration is called APLANATIC. Chromatic aberration may be corrected by combining two or more lenses of different kinds of glass. When so corrected the combination is called ACHROMATIC. A lens system that has been corrected for three different wave lengths (colors) is known as an APOCHROMATIC.

Compound microscope. The compound microscope consists essentially of a short focus objective lens (B, Fig. 5) which forms a magnified real image of the object (O), at (I_1). This image is then viewed through a magnifying or ocular lens (C) which forms a virtual image at (I_2). The distance (BI_1) is about the tube length (L) of the microscope. The TOTAL MAGNIFICATION is $25/F \times L/f$ where (F) and (f) are the focal lengths respectively of the ocular and the objective, all in cm.

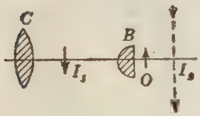

FIG. 5.

In practice an objective may be designated either by its equivalent focal length, f, (in millimeters) or by its magnifying power, 250 mm./f, (Zeiss) or by its initial magnification, L/f (Spencer, Bausch and Lomb) where (L) is conventionally 180 mm. or, sometimes, 160 mm. When the initial magnification is given, the total magnification of the microscope is obtained by multiplying by the power (250 mm./F) of the ocular which is usually stamped upon it, *e.g.*, $5x$ or $10x$.

Depth of focus. With a small aperture the diffusion circle or cross section of the cone of light near the image (I) of a point (Fig. 6, a), does not change much from (a) to (b) so that it is possible to change the focus up or down quite a little without the image losing much in sharpness. With a large aperture (Fig. 6, b), the diffusion circle at (a') or (b') is large, and hence it is not possible to go more than a little way from the true focus without losing distinctness. The depth of focus varies inversely as the magnification and the numerical aperture.

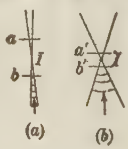

FIG. 6.

Aperture. The resolving power of a microscope or its ability to resolve the details of an object, is determined by the angle of the cone of light proceeding from a point in the object to the objective. This angle, commonly designated by $2u$, is called the angular aperture of the objective. The measure of the optical power is the sine of half this angle. In case an immersion fluid is used the power is increased n times, n being the index of refraction. This expression is called the numerical aperture (N. A.) Thus N. A. = $n \sin u$ where $n = 1$ for air 1.33 for water and 1.52 for oil of cedar (homogeneous immersion).

The measure of the RESOLVING POWER of an instrument is taken as the distance apart of two points which can be seen as separated. This distance at the maximum is $\lambda/2$ N.A., where λ is the wave length of the light used. For white light λ is about $561\mu\mu$ ($1\mu\mu = 10^{-6}$ mm.), for blue light $\lambda = 486\mu\mu$, for ultra-violet $\lambda = 250\mu\mu$. A slightly greater defining power is thus gained by the use of shorter wave lengths but the employment of ultra violet light requires the use of quartz lenses instead of glass.

Illumination. For the study of opaque objects and when employing low powers, light is thrown upon the object from above either by an outside mirror

or a condensing lens, or the microscope may be supplied with a special reflecting device called a vertical illuminator. In order to make full use of the numerical aperture of high power objectives the microscope must be provided with a sub-stage condenser, as carefully corrected for aberrations as the objective and ocular, of sufficient numerical aperture, capable of variation by means of an iris diaphragm. If daylight is not available, nitrogen lamps with special glass filters may be obtained, which give its equivalent.

Dark-field illumination is secured by making the course of the light from the condenser so oblique that although it cannot enter the objective directly, a portion is so scattered by the object as to make parts of its structure appear bright on a dark field.

Ultramicroscope. When dark-field illumination is carried to the extreme limit by using sunlight or the electric arc, the instrument is known as the ultramicroscope. The limit of visibility in the ordinary microscope is about 150 $\mu\mu$ (1 $\mu\mu = 10^{-6}$ mm.) while that of the ultramicroscope is about one hundredth of this. The smallest particle that has been detected is one of gold, estimated to be 1.7 $\mu\mu$.

Stage micrometer is a convenient scale, say 0.1 mm. divided to tenths, ruled on a cover glass and used as a microscope object. To DETERMINE THE MAGNIFICATION OF A MICROSCOPE take two visiting cards and rule a heavy black line across each. Place a stage micrometer under the microscope and focus it. Support one of the cards on a block at the side of the microscope in a plane perpendicular to the axis and at a distance of 25 cm. from the eyepiece. Look through the microscope with one eye and observe the card with the other. Adjust the card so that the line seen with one eye coincides with the image of one of the rulings on the stage seen with the other. Move the head slightly from side to side and observe if the image remains stationary with respect to the card. If it does not the image is not formed in the plane of the card and the focus must be altered until the parallax disappears. Then place the second card by the side of the first and slide it so that the line upon it coincides with another ruling of the image. Measure the distance apart of the card lines with a pair of dividers. The ratio of this distance to the known distance of the rulings on the stage micrometer is the magnification.

Camera lucida. The camera lucida is a reflecting prism attached to the microscope tube so that the image of a card or sheet of paper placed at a distance of 25 cm. appears superposed upon the image of any object seen through the microscope. It is useful for drawing the outlines of objects under investigation. Care must be used to have the field of the microscope and the surface of the paper about equally lighted.

To use the camera lucida for getting magnification, adjust the card so that its image coincides with the image of any two lines upon the stage micrometer. The axis of the microscope may be either horizontal or vertical or inclined, depending upon the type of camera used. With the points of the dividers upon the card adjust their separation so that they appear to coincide with the image of the lines upon the stage micrometer. The ratio of the spread of the dividers to the known distance of the lines is the magnification.

Micrometer eyepiece is a scale ruled upon glass so that its image formed by the eye lens coincides with the image under observation in the microscope. The readings must be calibrated for the exact conditions under which each objective is used. This is readily done by a direct observation of the number of lines on the ocular scale corresponding to one division of a stage micrometer, for that particular objective and position of the draw tube.

Filar micrometer is a micrometer eyepiece having a fixed and a movable cross wire that is carried across the field by means of a fine-pitched screw with a graduated head. The number of complete revolutions may be counted upon a comb which appears in the field, and the value of one of the graduations on the head may be found by counting how much it is necessary to revolve the head to move the cross wire a known distance, say from the image of one of the divisions of the stage micrometer to the next.

Index of refraction. The velocity of light is, in general, different in different media. The ratio of the velocity V_1 in one medium to that in another V_2 is called the relative index of refraction N_{12}, always taken in such sense that

the ratio is greater than unity. Thus $N_{12} = V_2/V_1$. As commonly stated, the index of refraction n of a medium is taken relative to air.

When light passes obliquely from air to another medium the direction changes in a manner given by the relation $n = \sin i/\sin r$ (Fig. 7) where i is called the angle of incidence and r is the angle of refraction, each being measured from the normal PP' to the surface. The index of refraction is also a function of the wave-length, being greater for short than for long waves. Consequently a beam of white light generally appears colored after refraction. This differential effect of refraction is termed DISPERSION. When any translucent object immersed in a liquid is viewed through a microscope the image will appear bounded by a colored fringe unless both the liquid and the substance have the same index of refraction. The refractive index of a substance can be determined by immersing it successively in a series of liquids whose indices of refraction are known until one is found in which the colored fringe disappears. Similarly if a series of transparent solids whose indices of refraction are known be given, the refractive index of an unknown liquid may be ascertained.

FIG. 7. Refraction

Method of displacement of image. When a point (O, Fig. 8) in any medium is viewed normally through a plane boundary AB in air, the apparent depth CO' of the point is less than the actual distance, depending upon the index of refraction. If these distances are measured, for example by focusing first on O then on O', the index of refraction will be given by $n = CO/CO'$.

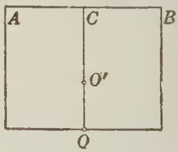

FIG. 8.

Polarization. Light that has been so modified by passing through a crystal that its vibrations are rendered parallel to a plane is called PLANE POLARIZED LIGHT. A beam of such light shows different properties on different sides of its line of propagation, so that it is more copiously reflected in some directions than in others, or it will be transmitted by a transparent crystal section in one position and extinguished by it in another. Any apparatus for thus modifying light is called a POLARIZER. It is usually a divided crystal of calcite called a NICOL PRISM. A similar prism used to test whether the light is polarized is called the ANALYZER. When the planes of polarization of the nicols are parallel, the field is light; when perpendicular (CROSSED), dark.

Micropolariscope. In microscopic work a pair of nicols which may be attached to the instrument is used to test whether a substance is double refracting or not, and thus assist in identification of a specimen. When a double-refracting substance is introduced into the dark field between crossed nicols the light is restored and sometimes colored. In particular circumstances, as with a thin plate of mica or selenite, the color changes as the analyzer is rotated.

10. Electrical phenomena and definitions

Definitions. Electric charges are of two kinds only, POSITIVE, obtained, *e.g.*, on a glass rod rubbed with silk, and NEGATIVE, obtained when a hard-rubber rod is rubbed with wool. The characteristic of these charges is that small bodies charged with like signs repel and with unlike signs attract each other. Any region through which electric forces act is called an ELECTRIC FIELD. A line through the field that has everywhere the direction in which a

positively charged point would be urged is called a LINE OF FORCE. Lines of force always start from positively-charged surfaces and run to negatively-charged surfaces. The magnitude of the force with which a positive-point charge is urged is called the INTENSITY OR STRENGTH OF THE FIELD at any place. The work that would be done by the forces of the field in moving a unit positive charge from one point to another is called the DIFFERENCE OF POTENTIAL between the two points. Since positive charges are urged from places of high to places of low potential, difference of potential, or electromotive force, may be regarded as difference of electrical pressure. The practical unit of potential is called the VOLT. The difference of potential between the copper and the zinc of a Daniell cell (also called the gravity or blue-stone battery) is about one volt.

A body that permits passage of an electric charge is called a CONDUCTOR, *e.g.*, metals and gas carbon; a body that prevents passage of an electric charge is an INSULATOR. Gases, gums and glass-like bodies are examples.

When a conductor is brought into contact with a second and charged body, the first body becomes immediately charged with the same sign as the second. When an insulator is touched to a charged body there is also a transfer of a certain amount of the charge but the electrification of the insulator is confined to the region of contact, except in so far as this charge may slowly creep over the surface, which may be very slightly conducting.

When any body is brought near an electric charge the nearer side of the body becomes electrified with the opposite sign to the original charge, and the farther side with the same sign. This ability of a charged body to influence another through an insulating medium is called ELECTROSTATIC INDUCTION and the medium in this sense is called the DIELECTRIC since lines of force can exist only in a non-conducting medium.

The phenomenon of induction may be differently described as follows: When any body is brought into an electric field it shows a negative charge where the lines of force meet its surface and a positive charge where they leave it. This induced charge is greatest on a conductor and least on an insulator. It also depends upon a constant of the insulating medium surrounding the body, which is called the SPECIFIC INDUCTIVE CAPACITY or DIELECTRIC CONSTANT of the medium. This constant is referred to air, or strictly to a vacuum, as unity. Thus to charge two paralleled metal plates to a difference of potential of one volt will take several times as much charge when they are separated by glass as when they are separated by air. The dielectric constant of ordinary insulators ranges from about 1 to about 10. When a non-conducting body is brought into an electric field the induced surface charge depends upon the dielectric constants inside and outside the body.

If a small metal body is brought near a charged body it will, as a whole, be attracted because the attraction of the nearer induced and unlike charge is greater than that of the farther like charge, the law of the action of two-point charges being inversely as the square of the distance. When the first body touches the second body it will receive a like charge and then be repelled. For a similar reason a small body such as a piece of paper or quartz will first be attracted to a charged body but when it makes contact there will be no new distribution of the charges, if its surface is a very perfect insulator, and it will cling to the charged body. These principles are made use of to separate metallic particles and grains of different dielectric capacity.

Power of points. When a conductor having sharp points is strongly electrified the surface charges are highly concentrated at the points and the field about them is intense. Particles of air are first attracted to contact and then so strongly repelled that they produce a stream of electrified wind in the vicinity, which discharges the conductor and may convey the charge to neighboring bodies. Electrostatic machines are often provided with

a series of points by which electricity is thus transferred from one part to another without actual contact of the parts.

Magnetism. A body that possesses a selective attraction for particles of iron is called a MAGNET. Magnetic phenomena may be conveniently described in terms of surface charges of positive and negative magnetism. An elongated magnetic needle behaves as if these hypothetical charges were concentrated about the ends, which are termed poles. If such a needle be suspended so as to turn freely in a horizontal plane, it will take a position approximately north and south. The end that points north is called the north pole. Positive magnetism is consequently called NORTH MAGNETISM and its opposite, SOUTH MAGNETISM. The behavior of magnetic charges is analogous to electric charges except that there are no conductors of magnetism and consequently it is impossible to magnetize a body entirely with north magnetism or south magnetism. With this exception all the phenomena and definitions given for electricity have their complete analogues in magnets and the magnetic field. The law of attraction or repulsion of two poles, the law of the inverse square of the distance, the passage of lines of force between poles, and the magnetization of a body by induction when placed in a magnetic field, are identically of the same form as in the electrical case. The ability of magnetic lines of force to pass through a body is called the PERMEABILITY of the substance but the permeability of most substances except those of the iron group differs little from air. Compared to the dielectric constant whose maximum value is about 10, the permeability of iron may reach 3000. This taken with the fact that there is no magnetic leakage by conduction readily explains why the total values of magnetic attractions may be made so much greater than electrostatic. Magnetic fields can be produced by the passage of an electric current through a conductor, the lines of force forming closed rings about the conductor. For this reason strong fields, or electromagnets, are easily varied and controlled. The separation of magnetic from non-magnetic mineral grains when placed in a magnetic field is based on these principles.

11. Electrochemical theory

Electrons. Electricity does not appear to be distributed continuously through bodies but in the form of discrete charges. The smallest known quantity of negative electricity has a mass, or is associated with a mass about $\frac{1}{1800}$th of the hydrogen atom. It is the same from whatever source derived and is called an ELECTRON. The electronic charge is $e = 4.7(10)^{-10}$ electrostatic units, and its mass $8.8(10)^{-28}$ gram. The hydrogen atom has a mass of $1.6(10)^{-24}$ gm. Positive electricity on the other hand does not appear to be associated with particles smaller than the atom, and this positive charge is always some multiple of the negative electron.

Atoms. Assume that the neutral atom (of atomic weight roughly $2N$) is a complex structure of N electrons grouped about a positive nucleus having a charge Ne, e being the value of the electronic charge. Assume further that a few of these electrons, called valence electrons, are arranged in the outer shell of the atom so that they may be readily detached. A positively-charged atom is then an ordinary atom which has been deprived of one or more electrons, and a negative atom is one which has acquired one or more free electrons. A MOLECULE is a stable, uncharged group of atoms. Its stability appears to depend upon the grouping of the electrons about the positive nuclei. A charged atom or group of atoms is called an ION.

Valency. The number of electronic charges which an atom carries when it becomes an electrolytic ion may be termed the valence of the ion, but it is not easy to say how many valence electrons an atom possesses, for the atom of an element may sometimes be positive and sometimes negative. The positive charge is the result of the loss of one or more electrons and the negative charge is due to the acquisition of electrons. Thus chlorine has a negative valence 1 in HCl, and a positive valence 7 in Cl_2O_7. Likewise carbon has a negative valence 4 in H_4C and a positive valence 4 in CO_2. In any such grouping the valence electrons can hardly be regarded as particularly belonging to either or any of the atoms which they join.

Electrolysis. When an electric current passes through certain liquids known as ELECTROLYTES, notably aqueous solutions of acids or salts, certain elements of the solution appear, or are set free at the plates (ELECTRODES) by which the current enters or leaves the liquid. The former, or positive electrode, is called the ANODE and the other, or negative, the CATHODE. The amount of any element liberated at one of the electrodes is proportional to the quantity of electricity that has passed, to the atomic weight of the element, and inversely as the valence. This law is simply explained by the view that the liquid contains carriers or IONS such as have been previously described, which are sorted out by the charged electrodes, the latter serving to maintain an electric field in the liquid; the positively charged ion (CATION) is repelled from the anode and attracted to the cathode, the negatively charged ion (ANION) is urged in the opposite direction.

This conclusion is still valid when the ion is not liberated, for here the ion instead of itself being set free enters into combination and releases a chemically equivalent amount of some other substance. Thus in HCl the ions are H^+ and Cl^-; when this is electrolyzed with platinum electrodes, the hydrogen ions migrate to the cathode where, by a rearrangement of electrons, a positive charge is given to the metal and a hydrogen molecule is liberated. In a similar manner Cl is set free at the anode. In a solution of sulphuric acid the ions are HH^{++} and SO_4^{--}. When this solution is electrolyzed there is this difference, that after the ion has given up its charge to the anode a combination of SO_4 with the water is effected forming a new molecule of H_2SO_4 which remains in solution while at the same time O_2 is set free.

Gas pressure. The relation between the pressure, volume, and temperature of a gas is given by $p = R\rho T/M$ where ρ is the density, T the absolute temperature, M the molecular weight (the ratio of the mass of the gaseous molecule to the mass of the hydrogen atom) and R is a UNIVERSAL GAS CONSTANT. If ρ is measured in grams per cubic centimeter, T in degrees C., that is, $T = t_c + 273$ where t_c is the Centigrade temperature, R has the value $8.31(10)^7$ ergs/gm./1° C. for all gases. The pressure p of a gas is regarded as arising from the impact of the molecules against the walls of the containing vessel.

Osmotic pressure. When two gases such as hydrogen and carbon dioxide are separated by a porous plate, *e.g.*, plaster of Paris, the pressure on the CO_2 side rises as a result of the more rapid diffusion of the smaller and more active hydrogen molecules through the pores of the plate. A somewhat analogous experiment may be arranged in the case of liquids. If, for example, an aqueous solution of sugar be separated from pure water by a semi-permeable membrane or partition that allows the water molecules to diffuse through it, but stops the passage of the solute molecule, the level on the side of the solution will rise until a considerable difference of pressure is established between the two sides. This difference is called the OSMOTIC PRESSURE. In dilute solutions this pressure is that which would be produced by the same number of independent particles existing in the gaseous form, *i.e.*, if these independent particles were molecules, the pressure would be given by an equation analogous to the gas law $p = RcT/M$ where c is the concentration in grams per cubic centimeter.

This equation is used to test whether the particles in solution are the same in number as the molecules.

Concentration of solutions. In electrochemical work a mass of a substance equal to its molecular weight is called a GRAM-MOLECULE or briefly 1 MOL. Thus a gram-molecule of H_2SO_4 is $2 + 32.07 + 64 = 98.07$ gm. The concentration of solutions is frequently stated in gram-molecules per liter of solution. One mol. per liter is called a MOLAR solution. Thus a molar solution of sulphuric acid would contain 98.07 grams of H_2SO_4 per liter. A NORMAL solution is usually defined as the molar solution divided by the valence of the highest ion. In the case of sulphuric acid the valence of SO_4 is 2, whence a normal solution would be ½(98.07) grams of H_2SO_4 per liter.

Freezing and boiling points. Another effect of a substance dissolved in water is to produce a change in the vapor pressure, and, in consequence, a lowering of the freezing-point and a raising of the boiling-point. This effect is directly connected with the concentration and the molecular weight and hence may also be used to test the equivalence of the number of the dissolved particles with the number of molecules.

Electrolytic dissociation. When a dilute solution of a non-electrolyte is formed in water, it is found that the resulting osmotic pressure and the changes of the freezing- and boiling-points are in satisfactory agreement with the laws just stated, but that dilute solutions of electrolytes show effects indicating the presence of a number of dissolved particles much greater than that of the solute molecules present, whence the conclusion is to be drawn that the molecules have split up into ions. Of all solvents water is the most effective in producing this dissociation. This has been attributed to the high dielectric constant of water. The law of attraction between two small charged particles is $F = Q(-Q)/Kr^2$, K being the dielectric constant and r the distance between them. Thus as K is increased the attraction between two ions of a molecule would become lessened.

Voltaic electromotive force or potential difference. If two different metals are immersed in an electrolytic solution they become charged and possess a definite difference of potential, which is the electromotive force of the ordinary electric battery. Nernst's explanation is that when a metal is placed in water there is a tendency for the metallic ions to go into solution and as these are always cations, *i.e.*, positively charged, they take this charge with them and leave the metal negatively charged with respect to the solution. The amount of metal actually dissolved is extremely small because the charges on the ions are so large that they soon create an electric field which prevents any more ions leaving the plate. The amount of metal to bring this about, may not, in fact, be sufficient to form a layer one molecule thick. The osmotic pressure exerted by the ions in solution when equilibrium has been attained is considered by Nernst to be a measure of what he terms SOLUTION PRESSURE or the tendency of the ions to go into solution. When on the other hand a metal is placed in a solution already containing a considerable number of ions and exerting an osmotic pressure greater than the solution pressure, this excess of pressure tends to drive some of the ions out of solution, in which process they give up a positive charge to the plate. In this case the plate becomes positively charged with respect to the solution. Thus a copper plate becomes positively charged to +.60 volt when immersed in a normal solution of copper sulphate. Zinc, on the other hand, having a greater solution pressure, becomes negatively charged to −.51 volt when immersed in a normal solution of zinc sulphate.

In a Daniell or gravity cell a plate of Cu and a plate of Zn, each immersed in a solution of its own salt, are combined so that the total electromotive force is the sum of these two differences of potential, *i.e.*, the copper or positive pole is about 1.11 volts higher than the zinc or negative pole. Similar conclusions apply to hydrogen as to metallic ions, since these tend to go into solution as positive ions. When any solution containing hydrogen ions is electrolyzed, the effect of the electric field is to drive them out of the ionic into the gaseous form at conducting surfaces where the force is directed away from the liquid. The theory not only explains the deposition of metals and the evolution of gas at the electrodes but may be applied to the spontaneous decomposition of water by alkali metals. Thus potassium has so great a solution pressure that the resulting electric force or osmotic pressure is sufficient to liberate hydrogen, since there are always a number of hydrogen ions present in water.

12. Surface tension

Every liquid surface behaves as if it were under tension and in some respects like a stretched elastic membrane. It differs in its behavior from such a membrane in three particulars: (1) It tends to contract indefinitely; (2) the tension is the same in all directions in the surface; (3) the tension is independent of the thickness as long as the latter exceeds a certain small value of the order of $70\mu\mu$ [$1\mu\mu = (10)^{-7}$ cm.]

Surface tension is explicable in terms of the molecular forces that hold a body together; frequently called cohesion or adhesion. Consider a small sphere, whose radius is within the range of molecular forces, to be drawn about a particle in the interior of a liquid. On account of the symmetry of the forces exerted by the other particles of the sphere, the one at the center will be in equilibrium. If, on the other hand, a similar sphere be drawn about a particle at the surface of the liquid, there will be a resultant force on the particle tending to draw it into the interior. This tendency of the surface particles to be drawn inward makes the surface behave as if it were under tension, whence it is convenient to speak as if there were a tensile force acting in the surface. The phenomenon of surface tension is often called CAPILLARITY. Surface tension is a property of an interface or boundary between unlike phases. A thin layer or sheet of liquid having two surfaces is called a FILM.

Measure of surface tension. The force necessary to keep a surface from contracting divided by the width of the surface at right angles to the applied force, is taken as the measure of surface tension T. In the c.g.s. system it is the force in dynes necessary to hold a ribbon of the surface 1 cm. wide from contracting.

Surface energy. Surface phenomena may be considered in terms of surface energy. If two parts of a body originally united are separated against their mutual molecular attractions, a certain amount of work must be done which may be recovered when the surfaces are again allowed to unite. Thus, every square centimeter of a surface may be regarded as the seat of an amount of energy. Whenever the surface of a body, as for example, a liquid, is increased by stretching, a definite amount of work is done, and when this area is contracted, the same amount of work is recovered. This work is easily shown to be numerically equal to the surface tension. Accordingly if A is the area of a surface, the total energy is $W = TA$. Since potential energy tends to a minimum, every liquid surface tends to become as small as the boundary conditions permit, or if the potential energy can diminish by a change in its chemical constitution, or in the concentration of the components of a solution, this change will occur spontaneously.

Angle of contact. When two fluids are in contact with a solid, these surfaces are found experimentally to meet at an angle which is called the angle of contact. In Fig. 9, *a*, let the interfacial tensions be denoted by the letters with subscripts, and the angle of contact of the oil-water surface with the solid by, θ. The condition of equilibrium is $T_{SO} = T_{SW} + T_{OW} \cos \theta$. When the molecular attraction between two substances is large, the intimacy of contact is also great and the interfacial energy or tension is small or may even become negative, in which case the liquid W will tend to spread indefinitely over the solid. In the case illustrated observation shows that water wets the solid, since $T_{SW} < T_{SO}$, or a given area of the solid covered with water represents less energy than the same area covered with oil. If $T_{SO} > T_{SW} + T_{OW}$ the liquid W would tend to cover the solid completely. In Fig. 9, *b*, the oil tends to displace the water. If $T_{SW} > T_{SO} + T_{OW}$ the liquid (O) would tend to cover the solid completely.

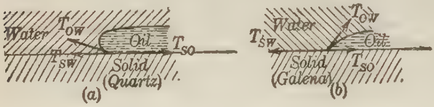

Fig. 9.

Molecular range. The distance at which molecular forces cease to be perceptible is of the order of $50\mu\mu$.

Tension of thin films. No change in the tension of a film occurs until its thickness is reduced to the order of $70\mu\mu$. Tension then first diminishes and afterward increases as the film gets thinner, reaching a stable value at about $12\mu\mu$ which is the thickness of the so-called "black-spot"; below this tension diminishes indefinitely as the thickness gets less. In the case of a thin film of oil on water the surface tension increases slightly as the film is thinned until a thickness of $2\mu\mu$ is reached, which is the thickness required to stop the motion of camphor particles. Between $2\mu\mu$ and $1\mu\mu$ tension increases about 28 per cent. and thereafter but slightly.

Temperature. Diminution of surface tension with increasing temperature, t, is given by the relation $T = T_0 - at$ where T_0 is the tension at 0° C., and a is a constant. For water $a = 0.152$ and for mercury 0.379 dynes per cm. per degree Centigrade.

Surface tension of solutions. Since water has a surface tension which is large compared to that of most ordinary substances, the common effect of a contaminant is to lower the tension, often to a marked degree; this result is intimately bound up with the production of the colloid state. As salts, however, have greater surface tension than water, the surface tension of aqueous salt solutions is generally greater than that of water and increases linearly with the concentration.

Surface concentration. Substances in solution that lower the surface tension of a liquid will concentrate at the surface and substances like salts that raise the tension tend to leave the surface layers. For this reason the presence of a salt does not produce a large increase in surface tension while, on the other hand, substances that reduce surface tension may produce large diminution. Any change in concentration at a surface is called ADSORPTION.

Stability of films. A contaminated surface can adjust so as to effect equilibrium under circumstances where a film of pure liquid would break, *e.g.*, a vertical film of pure liquid would thin down under the influence of its weight until it broke; if, however, the film contained a contaminant which by thinning out increased the surface tension, equilibrium might be regained.

Table 12. Surface tensions of electrolytes

(Solution in water for which T = 75.3 dynes per cm.; temperature, 18° C.; concentration, 1.5 gram-molecules per liter)

HNO_3	74.2	KNO_3	76.9
HCl	74.9	KCl	77.6
H_2SO_4	76.0	K_2CO_3	79.9
NaOH	78.3	$NaNO_3$	77.2
KOH	78.0	NaCl	77.8
NH_3	72.2	NH_4NO_3	77.0

Table 13. Surface tensions

Liquid	Temperature C°	Surface tension dynes per cm.	Liquid	Temperature C°	Surface tension dynes per cm.
Acetic acid	20	23.5	Paraffin oil	25	26.4
Alcohol, ethyl	20	16.5	Sulphuric acid sol., d = 1.14	15	74.4
Alcohol, methyl	20	23.0	Turpentine oil	15	27.3
Ammonia sol., d = 0.96	15	64.7	Pine oil	....	30.0
Benzene	17.5	29.2	Water	15	74.4

Liquid hydrogen	−252	2	$NaNO_3$, fused	339	106
Liquid oxygen	−183	13.1	HCl solution, d = 1.09	20	74.5
Liquid nitrogen	−196	8.5			
Olive oil	20	32			

Table 14. Interfacial tensions

	Temperature C°	Tension, dynes per cm.
Water-benzene	20	33.6
Water-chloroform	20	29.5
Water-ether	20	12 2
Water-olive oil	20	20.6
Water-paraffin oil	20	48.3
Mercury-water	20	427
Mercury-alcohol	20	399
Mercury-chloroform	20	399
Kerosene-water	....	32.8
Kerosene and pine oil—water	....	11.6
Kerosene and pine oil—0.05% sol. NaOH	....	7.3
Kerosene and pine oil—0.20% sol. NaOH	....	4.5
Kerosene and pine oil—0.20% sol. H_2SO_4	....	13.2
Coke-oven oil—water	....	14.1
Coke-oven oil—0.05% sol. NaOH	....	5.8
Coke-oven oil—0.20% sol. NaOH	....	2.6
Coke-oven oil—0.10% sol. Na_2CO_3	....	6.6
Coke-oven oil—0.20% sol. Na_2CO_3	....	4.4
Coke-oven oil—0.40% sol. H_2SO_4	....	14.4
Coke-oven oil—0.01% sol. saponin	....	9.3
Coke-oven oil—0.01% sol. tannic acid	....	12.7

For this reason durable films must consist of a mixture of substances, *e.g.*, soap and water. High viscosity also aids durability.

Measurement of surface tension. Since the presence of the slightest trace of a contaminant may greatly alter the surface tension, measurements of this quantity are subject to considerable uncertainty and the results may depend on the method employed whether static or kinetic. Even greater uncertainties attach to the angle of contact.

Wilhelmy's method. A thin plate of very clean glass or metal is suspended vertically from one of the arms of a balance and weighed. The lower edge is then immersed in a liquid that wets the plate and the additional mass, m, determined which must be placed in the other pan to balance the pull on the plate partly immersed. Correction must be made, if necessary, for the effect of the fluid displaced. If l is the total length of the blade, θ the angle of contact and g the acceleration of weight, T is found from the equation $2lT \cos \theta = mg$.

Parallel plates. Comparative values of T may be found from the height of rise of liquids between clean parallel glass plates. Two such plates separated at the corners by thin sheet metal and held together at the middle are dipped into the liquids. The surface tensions are proportional to $h/\cos \theta$ where h is the rise and θ is the angle of contact.

Method of falling drops. Let m be the mass of the drop as it falls from a thin-walled tube, r the external radius. The surface tension may be computed by the formula $T = mg/fr$ where f is a constant which may be taken as 3.8 when the radius of tube lies between 0.3 cm. and 1 cm. If very accurate results are desired f must be determined first by experiments on pure water for which T may be taken as 74.4 dynes/cm. at 15° C.

A similar method may be used for determining the interfacial tension when one liquid is allowed to drop out of the tube into another liquid. Let T_{AB} be the interfacial tension, v the total volume of the liquid delivered, D_B the density of one fluid, and D_A the density of the other, f the constant factor and r the external radius of the tube from which n drops are detached. Then $T_{AB} = v(D_B - D_A)g/nrf$. If the effluent fluid does not wet the glass, r is to be taken as the inner radius of the tube. Relative values of the interfacial tensions of different solutions may be thus compared by counting the number of drops in which a given volume of the same fluid flows out into two solutions.

Emulsions. Starting with two liquids, either may be dispersed in the other, but to get a stable emulsion some substance must pass into the separating surface and form a coherent film. This film becomes concave on the side having the higher surface tension, and the liquid on the concave side becomes the internal phase. It is possible to change from an emulsion of oil in water to one of water in oil by changing the nature of the third component.

With sodium soap, oil assumes the internal phase in water while with calcium soap, the water becomes the internal phase in oil. Hydrous ferric oxide may come down as an unquestionable internal phase, or as a jelly, when it is probably the external phase. When water is the external phase, insoluble particles should not affect the surface tension; there should be no osmotic pressure and no diffusion except that due to Brownian movements. If, however, the particles are slightly soluble, all of the effects named may occur in slight degree. If the suspensions are electrified they will move to the cathode or the anode accordingly as they adsorb a positive or a negative ion. Also since this adsorption will in general be selective the nature of the ion will be important as well as the sign of the charge.

Structure. When water becomes the internal phase and the less mobile phase becomes external, the latter will have a honeycomb structure. A distinct change in surface tension and viscosity would be expected but since the less mobile phase is insoluble in the other there would be no appreciable osmotic pressure. As these phenomena are markedly exhibited by gelatine the conclusion is to be drawn that gelatine is the external phase in the so-called aqueous solution of gelatine. Since emulsoid sols are two-phase liquids and since, further, gels may be obtained from them by cooling or evaporation, the conclusion is forced that gels possess a structure similar to emulsoids. We may naturally picture two degrees of solution, the more concentrated one forming the highly viscous walls of the cells which contain the other more dilute solution. Jellies may also have a structure like a sponge when, since each is continuous, there will be neither internal nor external phases, but there is no good reason for assuming that all jellies are of this type.

SECTION 26

THEORETICAL MECHANICS

BY

W. R. LONGLEY

PROFESSOR OF MATHEMATICS, YALE UNIVERSITY

STATICS

1. Definitions

Mechanics is the science of motion. It considers the effects of the action of force upon the motion of material bodies. KINEMATICS treats methods of describing motion and involves only concepts of geometry and time. DYNAMICS treats of the effect of forces upon the motion of bodies. KINETICS deals with cases in which the state of motion is changed by action of forces. STATICS deals with cases in which no such change is produced.

These definitions are those used in a large majority of modern texts. A few writers use dynamics as a synonym for mechanics while others use it as a synonym for kinetics.

Force is an action (push or pull) exerted by one body upon a second body. Forces occur always in pairs; the body acted upon exerts an equal and opposite force on the body acting. A force is completely specified by its magnitude, direction and sense, and point of application. In case of rigid bodies, which suffer no change of shape or size, the point of application is not important. The PRINCIPLE OF TRANSMISSIBILITY OF FORCE asserts that a force that acts upon a rigid body may be considered to be applied to any particle of the body that lies in the line of action of the force.

Concentrated and distributed forces. While it is usual to speak of the point of application and action line of a force, these apply strictly to concentrated forces only. An actual force is always a distributed force whose place of application is a surface or a solid. When

a book rests on a table the supporting pressure of the table is applied over the surface of the book in contact with it. When the earth attracts a body the place of application is the three-dimensional space occupied by the body. A CONCENTRATED FORCE is one of finite magnitude whose place of application is a point. This ideal definition can not be fulfilled by an actual force, but the conception is useful and there are forces whose place of application is very small which may be considered as applied at a point. A DISTRIBUTED FORCE is regarded as made up of a large number of small concentrated forces, the combined effect of which, in ordinary problems, is equivalent to a single concentrated force. (See Art. 13.)

Graphical representation. A concentrated force is a vector quantity. It is represented graphically by a straight line the length of which indicates the magnitude of the force, while the direction of the force is indicated by the direction of the line and the sense by an arrow placed on the line. For graphic work two distinct diagrams are employed and a systematic notation is useful. A drawing that represents a body or a structure together with action lines of forces applied to it is a SPACE DIAGRAM. The VECTOR DIAGRAM is one in which vectors are drawn to represent the magnitudes and directions of the forces. In Bow's SYSTEM OF NOTATION forces in a space diagram are designated by lower-case letters placed each side of the line; in the vector diagram by the same capital letters placed at the ends. In Fig. 1 the action line of force W applied to beam at L is indicated by ab, while the magnitude and direction are shown by vector AB.

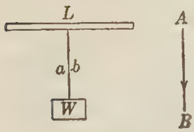

FIG. 1.

Classification of systems of forces is made according to the arrangement of their action lines. If the action lines lie in the same plane the system is COPLANAR, otherwise NON-COPLANAR. If they pass through the same point the system is CONCURRENT, otherwise NON-CONCURRENT. If two or more forces have the same action line they are COLLINEAR. A system of two equal forces, parallel, opposite in sense, and having different action lines is a COUPLE. Two or more forces equivalent to a single force are COMPONENTS of the single force. The single force is the RESULTANT of its components. In general, the resultant of a system of forces is the simplest equivalent system. This may be a single force, a single couple, or a force and a couple. When the resultant is a single force the EQUILIBRANT is a force equal in magnitude, having the same line of action but opposite sense. COMPOSITION is the operation of replacing a system of forces by its resultant. RESOLUTION is the operation of replacing a single force by a system of components.

2 Composition of two concurrent forces

Collinear forces form a special case of concurrent forces. The resultant of two collinear forces having the same sense is a force having the same action line, the same sense, and equal in magnitude to the sum of the magnitudes of the two forces. The resultant of two collinear forces acting in opposite senses is a force whose magnitude is equal to the difference between the magnitudes of the given forces and whose sense is that of the greater. The resultant of any number of collinear forces is a force having the same action line and equal in magnitude and sense to the algebraic sum of the components.

Parallelogram law. If two concurrent forces, P and Q (Fig. 2), whose action lines meet at O are represented in magnitude and direction by OA and OB, their resultant, R, acts along the diagonal, OC, of the parallelogram of which OA and OB are adjacent sides, and its magnitude is represented by the length of OC. This statement does not imply that O is the point of application of the forces. It is necessarily so with a particle (Fig. 2a). But with a rigid body

the point of application of a force may be any point of the body on the action line of the force (Fig. 2*b*). This law applies as well when the point O is outside the body (Fig. 2*c*).

Triangle law. If two concurrent forces, P and Q (Fig. 3), are represented in magnitude and direction by AB and BC, their resultant, R, is represented in magnitude and direction by AC, the third side of the triangle ABC. The action line of R is ac through the point of intersection of the action lines of P and Q. The resultant of two concurrent forces may be computed by trig-

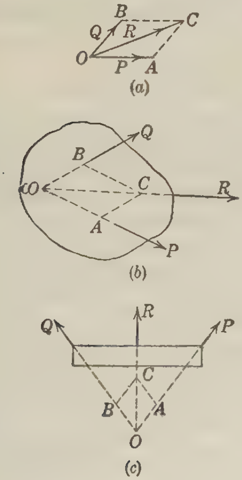

FIG. 2.

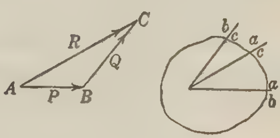

FIG. 3.

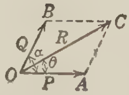

FIG. 4.

onometry. If α (Fig. 4) denotes the angle AOB between forces P and Q, and θ denotes the angle AOC between P and the resultant, R, then

$$R^2 = P^2 + Q^2 + 2PQ \cos \alpha \text{ and } \tan \theta = \frac{Q \sin \alpha}{P + Q \cos \alpha}.$$

Resolution of a force into two components can be made in an infinite number of ways. If a force, F, is represented in magnitude and direction by AB and if C is any point chosen arbitrarily, then AC and CB represent in magnitude and direction the two components whose resultant is the given force, F. The usual case of resolution demands that the two components shall be at right-angles to each other. The RECTANGULAR COMPONENT (or RESOLVED PART) of a force along any line, OX, (Fig. 5) is given by $F_x = F \cos \alpha$. It is understood

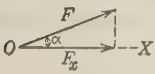

FIG. 5.

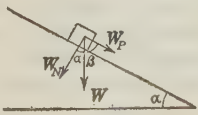

FIG 6.

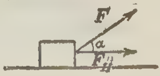

FIG. 7.

that angle α is measured in counterclockwise direction from the positive X-axis to the positive end of the action line of F. The resolved part of a force along any line represents the entire effect of the force in the direction of that line.

Example 1. The weight, W, of a body resting on an inclined plane (Fig. 6), exerts a pressure W_N normal to the plane equal to $W \cos \alpha$ and a force W_P parallel to the plane equal to $W \cos \beta = W \sin \alpha$.

Example 2. A body being dragged along a level plane by a force, F, making an angle, α, with the horizontal (Fig. 7) is urged forward by a force F_H equal to $F \cos \alpha$.

Analytic composition of two forces is accomplished by using rectangular components. If R is the resultant of P and Q and if R_x, P_x, Q_x, are components along the X-axis and R_y, P_y, Q_y are components along the Y-axis then $R_x = P_x + Q_x$ and $R_y = P_y + Q_y$. The resultant is inclined to the X-axis at an angle, θ, given by the formula $\tan \theta = R_y/R_x$. The magnitude of the resultant is $R = \sqrt{R_x^2 + R_y^2}$.

3. Composition of any number of concurrent forces

Coplanar forces. The resultant of any number of coplanar concurrent forces is found graphically by constructing a FORCE (OR MAGNITUDE) POLYGON according to the principle of the force triangle. Suppose the forces to be combined are F_1, F_2, F_3, F_4 whose action lines meet at O (Fig. 8). Beginning at A draw AB to represent F_1 in magnitude and direction, BC to represent F_2, CD to represent F_3, and DE to represent F_4. The resultant is given in magnitude and direction by AE and its line of action passes through O.

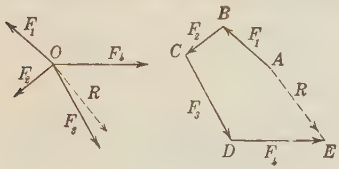

FIG. 8.

The resolved parts of a resultant in the directions of a pair of rectangular axes are obtained by adding the resolved parts of the components. Let R make an angle θ with the X-axis, F_1 the angle α_1, . . ., F_4 the angle α_4, where it is understood that all angles are measured in a counterclockwise direction from the positive X-axis. Then

$$R \cos \theta = R_x = F_1 \cos \alpha_1 + F_2 \cos \alpha_2 + \ldots = \Sigma F_x,$$

$$R \sin \theta = R_y = F_1 \sin \alpha_1 + F_2 \sin \alpha_2 + \ldots = \Sigma F_y,$$

$$R = \sqrt{R_x^2 + R_y^2}, \quad \tan \theta = R_y/R_x.$$

Non-coplanar forces. When the lines of action of a system of concurrent forces do not lie in the same plane the resultant may be found by constructing a space or skew polygon by the same method used for coplanar forces. For analytic work it is customary to use a system of three mutually perpendicular axes. The direction of a force is indicated by three angles α, β, γ (Fig. 9). These are the angles which the action line of the force makes with the X-, Y-, and Z-axes respectively, each angle being less than 180° and measured from the positive co-ordinate axis to the action line of the force. The resolved parts of the force are given by

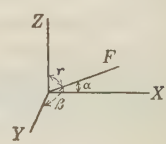

FIG. 9.

$$F_x = F \cos \alpha, \quad F_y = F \cos \beta, \quad F_z = F \cos \gamma.$$

The resultant, R, (direction angles α, β, γ) of a system of n forces, F_1 (direction angles α_1, β_1, γ_1), F_2, . . . F_n is found by the formulas

$$R_x = F_1 \cos \alpha_1 + F_2 \cos \alpha_2 + \ldots + F_n \cos \alpha_n = \Sigma F \cos \alpha,$$

$$R_y = F_1 \cos \beta_1 + F_2 \cos \beta_2 + \ldots + F_n \cos \beta_n = \Sigma F \cos \beta,$$

$$R_z = F_1 \cos \gamma_1 + F_2 \cos \gamma_2 + \ldots + F_n \cos \gamma_n = \Sigma F \cos \gamma,$$

$$R = \sqrt{R_x^2 + R_y^2 + R_z^2},$$

$$\cos \alpha = R_x/R, \quad \cos \beta = R_y/R, \quad \cos \gamma = R_z/R.$$

4. Moments and couples

Moment of a force with respect to (about) a point is the product of its magnitude and the length of the perpendicular from the point to its action line. Thus (Fig. 10) the moment of F about O is Fp. It is equal to twice the area of the triangle OAB. Point O is the CENTER OF MOMENTS and distance p is the MOMENT (OR LEVER) ARM. The moment of a force is the measure of its tendency to produce rotation about an axis passed through O in a direction perpendicular to plane OAB. This measure is expressed in terms of the units of force and length, as ft.-lb., in.-tons. (Some writers use lb.-ft. as the unit of moment of a force to distinguish from ft.-lb. as the unit of work and energy.) Moments are generally considered as positive when they tend to produce rotation in a counterclockwise direction and negative when the direction is clockwise. The moment of a force about a line or axis is found by resolving the force into two rectangular components, one of which is parallel to the line. The product of the perpendicular component and the distance from its action line to the axis is the moment of the given force about the given axis. The value of this moment does not depend on the point of application assumed for the force.

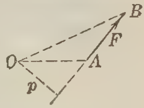

FIG. 10.

Composition of moments is based on Varignon's Theorem: The moment of the resultant of two concurrent forces about any point in their plane is equal to the algebraic sum of the moments of the two forces about the same point. The theorem is valid (*a*) if instead of two there is any number of forces, and (*b*) if the forces are merely coplanar without being concurrent. A similar theorem holds for moments about a line or axis.

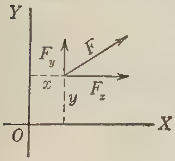

FIG. 11.

For analytic computation the moment of a force (Fig. 11) about the origin (or a line through the origin perpendicular to the XY-plane) is given by the formula:

$$M = xF_y - yF_x,$$

where (x, y) is any point on the action line of the force.

Couples. Two equal and parallel forces of opposite sense constitute a couple. The ARM OF A COUPLE is the perpendicular distance between the action lines. The PLANE OF A COUPLE is the plane determined by the action lines. The MOMENT (OR TORQUE) OF A COUPLE is the product of the magnitude of one of the forces and the arm. It is equal to the algebraic sum of the moments of the two forces of the couple with respect to any point in its plane. The moment is usually called positive if the forces tend to produce counterclockwise rotation, and negative if clockwise. The CENTER OF ROTATION for a couple may be anywhere in its plane. Two couples are equivalent if their planes are parallel and their moments equal. Hence a couple may be turned about in its own plane or moved to a parallel plane or replaced by another

couple (having an arm of any given length but the same moment) without altering its effect on a rigid body.

Resultant of couples. The resultant of any number of couples acting in the same plane or in parallel planes is a couple whose moment is equal to the algebraic sum of their moments. Composition of couples whose planes are not parallel is accomplished by vector addition. A couple is represented by a vector drawn perpendicular to its plane, the length of the vector (to scale) being equal to the moment of the couple. The vector points from the plane toward that side from which the rotation appears counterclockwise. This vector is sometimes called the AXIS OF THE COUPLE. Any number of couples may be combined by adding vectors representing them according to the parallelogram law. (See Art. 2.)

Resultant of single force and couple in the same plane (or parallel planes) is a single force equal and parallel to the original force, at a distance from it equal to the moment of the couple divided by the magnitude of the force; and so situated that the moment of the resultant about the point of application of the original force is of the same sign as the moment of the couple. The couple may be brought into the position shown in Fig. 12. The resultant of P, $-Q$, and Q is R $(=P)$ acting in a line through point C so that $(P - Q) \times AC = Q \times BC$ (See Art. 5). From this it follows that

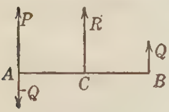

FIG. 12.

$$AC = \frac{Q(AC + BC)}{P} = \frac{\text{moment of couple}}{P}.$$

5. Resultants of parallel forces

Resultant of two parallel forces acting in the same direction is equal in magnitude of the sum of their magnitudes, is parallel to the forces, and divides the line joining their points of application in the inverse ratio of the magnitudes of the given forces. Thus (Fig. 13a) $R = P + Q$ and $P \times AC = Q \times BC$ or $aP = bQ$. Also $aR = cQ$ and $bR = cP$. The resultant of two unequal parallel forces acting in opposite directions is equal in magnitude to difference of their magnitudes, acts in the direction of the larger force, and divides the line joining their points of application externally in the inverse ratio of the magnitudes of the given forces. Thus (Fig. 13b) $R = P - Q$ and $P \times AC = Q \times BC$ or $aP = bQ$. Also $aR = cQ$ and $bR = cP$

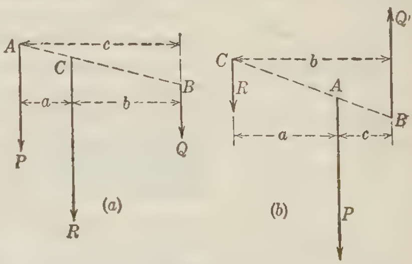

FIG. 13.

Two equal parallel forces acting in opposite directions form a couple (see Art. 4). The equations above show that when P and Q are nearly equal, R is very small and a and b are very large. As the magnitude of Q approaches that of P, R approaches zero and its line of action recedes to an infinite distance. This gives rise to the conception of a couple as equivalent to a force of zero magnitude with an infinite lever arm.

Moment of the resultant of any number of parallel forces in the same plane about any point in their plane is equal to the algebraic sum of the moments of the given forces about that point. In general, the algebraic sum

of the moments of any system of parallel forces about any axis is equal to the moment of the resultant about that axis.

Center of parallel forces is the point of application of the resultant. If the points of application of any system of parallel forces remain the same while the direction of the forces of the system is changed, the resultant will pass always through the center (or CENTROID) of the system (see Art. 13).

Center of two parallel forces may be found by the following construction (Fig. 14). Suppose A and B are the points of application of forces P and Q. From A lay off AA' equal to Q but in the opposite direction to Q. From B lay off BB' equal to P and in the same direction as P. The intersection C of AB and $A'B'$ is the center of P and Q.

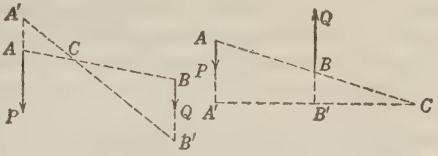

FIG. 14.

The magnitude of the resultant and the center of any system of parallel forces may be found by the following formulas. Using a set of rectangular axes, let the points of application of parallel forces $P_1, P_2, P_3, \ldots$ be (x_1, y_1, z_1), (x_2, y_2, z_2), (x_3, y_3, z_3), . . ., respectively, and let the point of application of the resultant R be $(\bar{x}, \bar{y}, \bar{z})$, then

$$R = P_1 + P_2 + P_3 + \ldots, \qquad \bar{x} = \frac{x_1P_1 + x_2P_2 + x_3P_3 + \ldots}{R},$$

$$\bar{y} = \frac{y_1P_1 + y_2P_2 + y_3P_3 + \ldots}{R}, \qquad \bar{z} = \frac{z_1P_1 + z_2P_2 + z_3P_3 + \ldots}{R}.$$

The sums in these formulas are algebraic sums; proper signs must be given to both coordinates and forces. The formulas are valid for all cases except when $R = \Sigma P = 0$. If the application points all lie in the same plane, this may be taken for the XY-plane and the last formula is unnecessary.

6. Resultant of any system of non-concurrent forces acting on a rigid body

The resultant of any system of forces acting on a rigid body may be (1) a single force, (2) a single couple, (3) a single force and a single couple. A system of coplanar forces can be reduced to either case 1 or case 2. Case 3 can occur only when the action line of the single force is not parallel to the plane of the single couple.

RESULTANT OF ANY SYSTEM OF COPLANAR FORCES

Graphic method. *Case* 1. The resultant is a single force. Suppose the forces to be compounded are ab, bc, cd, de shown in a space diagram (Fig. 15a). The magnitude and direction of the resultant are determined by constructing the force (or magnitude) polygon $ABCDE$ (Fig. 15b), in which AE is the resultant. The action line of the resultant is found by constructing a STRING (or FUNICULAR) POLYGON as follows. Point O (called the POLE) is chosen arbitrarily and rays OA, OB, OC, OD, OE are drawn. Then, using Bow's notation (see Art. 1), oa and ob are drawn, parallel to OA and OB, respectively, from any convenient point on ab; oc is similarly drawn from the point

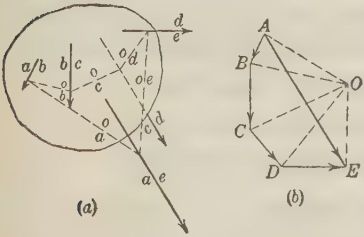

FIG. 15.

where ob meets bc; od is drawn from the point where oc meets cd; and oe is drawn from the point where od meets de. Then the intersection of oa and oe is a point on the action line of the resultant.

It may happen that oa and oe are parallel but, if the force polygon is not closed (see Case 2), this may be avoided by proper choice of point O.

Case 2. The resultant is a single couple. If the force polygon is closed (points A and E coincide) the resultant force is zero. Rays OA and OE coincide and oa and oe must be parallel. If oa and oe do not coincide, the string polygon is open and the resultant of the system is a couple. The moment of the couple is equal to the product of the force represented by OA and the perpendicular distance between oa and oe. If oa and oe coincide, the string polygon is closed and the resultant of the system is zero.

Analytic method. *Case* 1. The resultant is a single force. The magnitude and direction of the resultant may be computed as in the case of concurrent forces (see Art. 3):

$$R_x = \Sigma F_x, \quad R_y = \Sigma F_y, \; R = \sqrt{R_x^2 + R_y^2}, \; \tan\theta = R_y/R_x.$$

The position of the action line of the resultant is determined by the fact that its moment about any point must equal the sum of the moments of the component forces about that point. Thus if $M = \Sigma(xF_y - yF_x)$ denotes the sum of the moments of the given forces about the origin of co-ordinates, the action line of the resultant must be at distance M/R from the origin. The moment arm of R must be laid off in such a way that the sign of the moment of the resultant is the same as the sign of the sum of the moments of the given forces.

Case 2. The resultant is a single couple. In this case $R_x = 0$, $R_y = 0$. The moment of the resultant couple is equal to the sum of the moments of the given forces about any point. The value of this moment will be the same whatever point is chosen as origin.

RESULTANT OF ANY SYSTEM OF NON-COPLANAR FORCES

This is, in general, a single force and a single couple whose plane is not parallel to the action line of the force. The magnitude and direction of the resultant may be computed as in the case of concurrent forces (see Art. 3):

$$R_x = \Sigma F_x, \; R_y = \Sigma F_y, \; R_z = \Sigma F_z, \; R = \sqrt{R_x^2 + R_y^2 + R_z^2},$$

$$\cos\alpha = R_x/R, \; \cos\beta = R_y/R, \; \cos\gamma = R_z/R.$$

The point of application of the resultant force may be chosen arbitrarily. If the origin of co-ordinates is taken at this point, the resultant couple is the vector sum (see Art. 4) of the three component couples M_x, M_y, M_z, where

$$M_x = \Sigma(yF_z - zF_y) = \text{sum of moments about } X\text{-axis},$$

$$M_y = \Sigma(zF_x - xF_z) = \text{sum of moments about } Y\text{-axis},$$

$$M_z = \Sigma(xF_y - yF_x) = \text{sum of moments about } Z\text{-axis}.$$

7. Conditions of equilibrium

Definitions. A system of forces is in equilibrium if their combined action produces no change in motion of the body to which they are applied. There is no change in motion if the body remains at rest or moves in a straight line

with constant speed. A rigid body is in equilibrium if all the external forces acting upon it form a system in equilibrium.

Conditions of equilibrium may be expressed graphically by means of the force and string polygons or analytically by means of algebraic equations. In general, a system is in equilibrium if, and only if, the resultant force is zero and the resultant couple is zero.

System of concurrent forces is shown graphically to be in equilibrium if the force polygon closes. Analytically the sum of the components in two directions must be zero (see Art. 3.)

$$R_x = \Sigma F_x = 0, \quad R_y = \Sigma F_y = 0.$$

System of coplanar forces is shown graphically to be in equilibrium, if (*a*) the force polygon closes (indicating no effect of translation), and (*b*), if a string polygon closes (indicating no effect of rotation). Analytically three and only three independent equations can be written which are necessary and sufficient to insure equilibrium of a system of forces acting in the same plane. A set of three such equations may be written in three different ways. The system will be in equilibrium if (1) the sum of the components is zero for both of any two directions and the sum of moments about any one point is zero; (2) the sum of moments about each of two points is zero and the sum of the components is zero in a direction not perpendicular to the line joining these two points; (3) the sum of the moments is zero about each of three points not in the same straight line. Since only three independent equations can be written, it is possible to solve for only three unknown elements. When more than three elements of a system of coplanar forces acting on a single body are unknown the problem is statically indeterminate.

Non-coplanar forces. Statical problems arising in engineering practice seldom require the use of conditions of equilibrium in three dimensions. It is usually possible to simplify the problem by combining pairs of forces in such a way as to reduce the system to one plane (see Fig. 44). When it is necessary or desirable to use three dimensions, six equations are required to express the conditions of equilibrium. Using a set of rectangular axes these equations are (see Art. 6).

$$R_x = \Sigma F_x = 0; \quad R_y = \Sigma F_y = 0; \quad R_z = \Sigma F_z = 0;$$

$$M_x = \Sigma(yF_z - zF_y) = 0; \quad M_y = \Sigma(zF_x - xF_z) = 0;$$

$$M_z = \Sigma(xF_y - yF_x) = 0.$$

Special case. If three forces are in equilibrium they must be coplanar, and must be concurrent or parallel. If concurrent, each force is proportional to the sine of the angle between the other two; if parallel, each force is proportional to the distance between the other two.

8. Application of conditions of equilibrium

Problems in statics deal with bodies known to be in equilibrium under the action of a system of forces of which some elements are known and some are unknown. The solution of such a problem consists in finding the unknown elements. Success in solving problems in statics depends primarily on the proper choice of body or part of structure to which conditions of equilibrium are to be applied. This fact is emphasized in the examples that follow.

Simple examples. **1.** A body weighing 100 lb. (Fig. 16), suspended by a flexible cord, is pulled horizontally with a force of 40 lb. Determine the direction of the suspending cord and its tension.

The body to which the conditions are to be applied is the weight W in equilibrium under the action of three forces. The action lines of three forces must be concurrent and a moment equation is unnecessary.

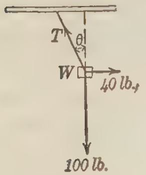

FIG. 16.

FIG. 17.

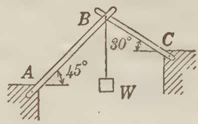

FIG. 18.

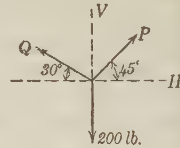

FIG. 19.

First method. Resolution into horizontal and vertical components gives H: $40 - T \sin \theta = 0$, and V: $100 - T \cos \theta = 0$, whence $\tan \theta = 0.4$, $\theta = 21° 48'$, $T = 107.7$ lb.

Second method. Force triangle. Since the force triangle must be closed for equilibrium, θ and T may be calculated from Fig. 17. The graphic method consists in measuring θ and T in the force triangle.

2. In Fig. 18 a horizontal pin B carrying a weight of 200 lb. passes through the members AB and BC inclined respectively at angles of 45° and 30° to the horizontal and held by horizontal pins A and C. Supposing the weights of AB and BC to be small and negligible, find the compression in each member.

The body to which the conditions of equilibrium are to be applied is the pin B which is in equilibrium under the action of three forces (Fig. 19).

First method. Resolution into horizontal and vertical components gives H: $P \cos 45° - Q \cos 30° = 0$, V: $P \sin 45° + Q \sin 30° - 200 = 0$, whence $P = 179.4$ lb. = compression in AB, and $Q = 146.4$ lb. = compression in BC.

Second method. A force triangle is drawn by first laying off (Fig. 20) a vector representing 200 lb. acting vertically downwards, then drawing lines making angles of 45° and 60°, respectively from the extremities of the vector and marking arrows to indicate that the triangle is closed. P and Q are found from the proportion $\frac{200}{\sin 75°} = \frac{P}{\sin 60°} = \frac{Q}{\sin 45°}$.

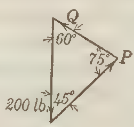

FIG. 20.

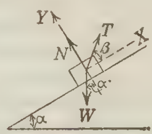

FIG. 21.

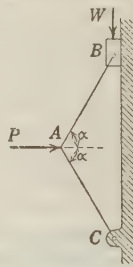

FIG. 22.

The graphic method consists in measuring P and Q in the force triangle.

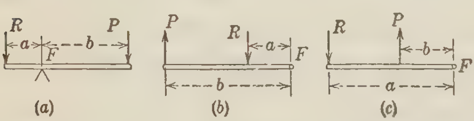

FIG. 23.

3. A body of weight W is held on a smooth plane inclined at angle α to the horizontal, by means of a cord making an angle β with the plane (Fig. 21). Find the tension T in the cord and the pressure on the plane.

The body to which the conditions of equilibrium are to be applied is the weight. N is the normal pressure of the plane on the weight. This is equal and opposite to the pressure of the weight on the plane. Taking an X-axis parallel to plane, the method of resolution gives X: $T \cos \beta - W \sin \alpha = 0$, Y: $T \sin \beta + N - W \cos \alpha = 0$, whence $T = W \sin \alpha \sec \beta$, $N = W(\cos \alpha - \sin \alpha \tan \beta)$.

4. A toggle joint is shown in Fig. 22. A force P is applied at A and a resistance W overcome at B. Find the ratio of P to W. (It is assumed that the weights of arms AB and AC can be neglected.) Let F denote the compression in each arm and consider the pin B. Taking vertical components: $F \sin \alpha = W$. Consider next the pin A. Taking horizontal components: $2F \cos \alpha = P$. Elimination of F between these equations gives $P = 2W \cot \alpha$.

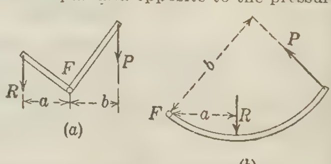

FIG. 24.

5. Levers are classified as follows: First class, fulcrum F between applied force P and resistance R (Fig. 23a); Second class, R between F and P (Fig. 23b); Third class, P between F and R (Fig. 23c). The relation between P and R is found by taking moments about F: $bP = aR$, where a and b represent perpendicular distances from F to the action lines of R and P, respectively. The same relation holds, if the lever is bent (Fig. 24a), or curved (Fig. 24b).

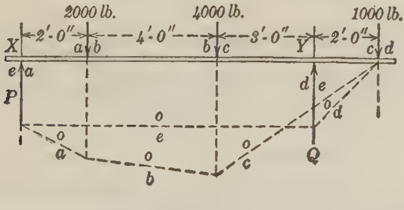

Fig. 25.

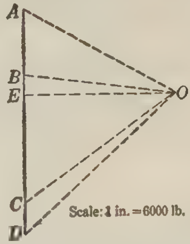

Fig. 26.

6. A beam is loaded as shown in Fig. 25 and supported at X and Y. Find the supporting forces P and Q.

Graphic method (see Art. 6). Since the forces are all parallel, the force polygon consists of segments of a straight line. Segments AB, BC, CD, DE, EA (Fig. 26), represent 2000 lb., 4000 lb., 1000 lb., Q, P, respectively. The location of E is to be determined by a string polygon. Rays OA, OB, OC, OD are drawn. Using Bow's notation (see Art. 1), and starting at point on the action line of P, the polygon oa, ob, oc, od, is drawn with closing line oe. Ray OE parallel to oe locates point E and the unknown forces are $Q = DE = 4330$ lb., and $P = EA = 2670$ lb.

Analytic method. To find P, moments are taken about Y: $2000 \times 7 + 4000 \times 3 - 1000 \times 2 - P \times 9 = 0$, whence $P = 2667$ lb.

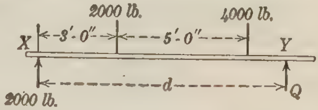

Fig. 27.

To find Q, moments are taken about X: $-2000 \times 2 - 4000 \times 6 - 1000 \times 11 + Q \times 9 = 0$, whence $Q = 4333$ lb.

As a check, the sum of the vertical forces must equal zero. $2667 + 4333 - 2000 - 4000 - 1000 = 0$.

7. A beam is loaded as shown in Fig. 27 and supported at X and Y. The reaction at X is 2000 lb. Find the reaction Q at Y and the distance XY.

Taking vertical components, $2000 - 2000 - 4000 + Q = 0$, whence $Q = 4000$ lb.

Taking moments about X: $-2000 \times 3 - 4000 \times 8 + Qd = 0$, whence $d = 9.5$ ft.

9. Pulleys

In Fig. 28, P denotes the force required to support weight W. If the pulleys were frictionless and if W were moving at a constant speed, this same P would be sufficient to continue the motion at this speed.

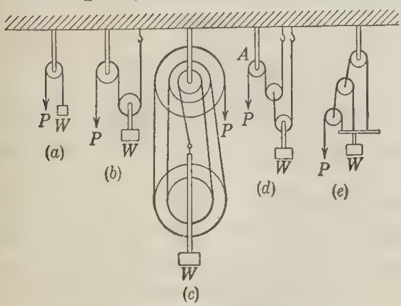

Fig. 28.

(a) Fixed pulley, $P = W$. The only advantage is the change of direction in which P is applied.

(b) Single movable pulley, $P = W/2$.

(c) Block and fall. Two blocks of pulleys of which the upper is fixed while the lower is movable, with a single cord passing alternately around the pulleys in the upper and lower blocks, the portions of cord between successive

pulleys being approximately parallel. If $n (n = 5$ in Fig. 28c) is the number of plies at the lower block, then $P = W/n$.

(d) If A is a fixed pulley and n is the number of movable pulleys, then $P = W/2^n$. In Fig. 28d, $n = 2$, $P = W/4$.

(e) If n is the number of cords attached to a bar supporting W, then $n - 1$ is the number of movable pulleys and $P = W/(2^n - 1)$. In Fig. 28e, $n = 3$, $P = W/7$.

In the relations between P and W given above no account is taken of the weights of the pulleys. In (b) and (c) the weights of the movable pulleys merely form part of the gross weight to be lifted. In (d) the movable pulleys have to be lifted but do not form merely part of the gross weight because only one has to be lifted the same distance as W. In (e) the movable pulleys descend and their weight assists P in lifting W.

10. Trusses

Definitions. A TRUSS is a jointed frame made up of straight bars connected at the ends by pins. Loads are applied only at the joints and, weights of members being neglected, the forces acting on any one member produce tension or compression stresses but no bending. Each member is a two-force piece with equal and opposite forces at each end. To insure rigidity under all conditions of loading the truss must be made up of a series of triangles. A COMPLETE FRAME (Fig. 29a) is made up of just enough bars to preserve the shape under all loads, and must be made up of the minimum number of bars consistent with being composed wholly of triangles. An INCOMPLETE FRAME (Fig. 29b) is not composed wholly of triangles and can carry only symmetrical or other specially arranged loads. A REDUNDANT FRAME has more bars than are necessary to preserve the shape. If both diagonals (Fig. 29c) are pin connected the frame is redundant. If the diagonals are designed to resist tension (or compression) only, the redundancy is only apparent as both diagonals will not be under stress at once. Stress in a redundant frame can not be determined by the laws of elementary statics.

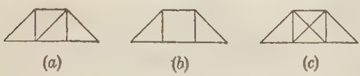

FIG. 29.

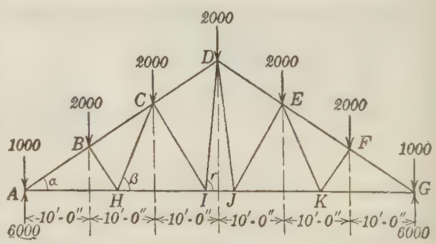
Elementary methods for calculating stresses in truss members are shown in the following examples.

1. *Method of joint resolution.* The roof truss (Fig. 30) has a span of 60 ft. and rise of 15 ft., each inclined upper chord being divided into three equal parts by normal struts. In each set of equations the body considered in equilibrium is the pin at the joint. For writing equations all members are assumed in tension. A plus sign with the answer indicates tension and a minus sign compression.

With loads at the joints of the upper chords as indicated, the supporting forces at A and G are found first and are 6000 lb. each.

Pin A. The horizontal and vertical components are: H: $AB \cos \alpha + AH = 0$, V: $AB \sin \alpha + 6000 - 1000 = 0$, whence $AB = -11{,}200$ lb., $AH = 10{,}000$ lb.

Pin B. The components along and perpendicular to BC are: $BC - AB - 2000 \sin \alpha = 0$, $-BH - 2000 \cos \alpha = 0$, whence $BH = -1800$ lb., $BC = -10{,}300$ lb.



$\sin \alpha = 0.447$, $\sin \beta = 0.800$ $\sin \gamma = 0.949$
$\cos \alpha = 0.894$ $\cos \beta = 0.600$ $\cos \gamma = 0.316$.

FIG. 30.

Pin H. The horizontal and vertical components are: $HI - AH + HC \cos\beta - BH \sin\alpha = 0$, $HC \sin\beta + BH \cos\alpha = 0$, whence $HI = 8000$ lb., $HC = 2000$ lb.

Pin C. The components along and perpendicular to CD are: $CD - BC - HC \cos\alpha - 2000 \sin\alpha = 0$, $-CI - 2000 \cos\alpha - HC \sin\alpha = 0$, whence $CD = -7600$ lb., $CI = -2680$ lb.

Pin I. The horizontal and vertical components are: $IJ - HI + ID \cos\gamma - CI \sin\alpha = 0$, $ID \sin\gamma + CI \cos\alpha = 0$, whence $IJ = 6000$ lb., $ID = 2520$ lb.

Stresses in the remaining members are found by symmetry.

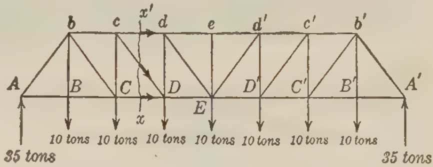


FIG. 31.

It should be observed that, in the preceding method, the order in which pins are considered is important. Before any one pin is considered it is necessary to know all but two of the forces acting on that pin. If this method is employed it is necessary to calculate stresses in all members in order to get stress in ID.

2. *Method of sections.* Fig. 31 represents a PRATT TRUSS of 240 ft. span having 8 equal panels of 30 ft. each and depth 40 ft. With the loading indicated (symmetrical spacing of the loads being assumed) the supporting forces at A and A' are 35 tons. Consider section xx'. The portion of the truss to the left of xx' is a rigid body in equilibrium under the action of three known forces at A, B, and C and three unknown stresses in cd, cD, and CD, which may be found by the conditions of equilibrium as follows: Taking moments about D (assuming the unknown stress as tension): $-40cd + 300 + 600 - 3150 = 0$, whence $cd = -56.25$ tons (compression).

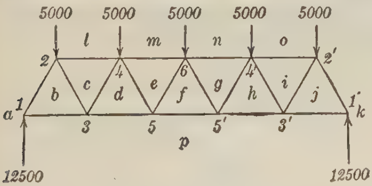

FIG. 32.

Taking moments about c: $40CD + 300 - 2100 = 0$, whence $CD = +45$ tons (tension).

Vertical components give $-0.8cD - 10 - 10 + 35 = 0$, whence $cD = +18.75$ tons (tension).

Stresses in other members may be found by using appropriate sections. The section must not cut more than three members in which stresses are unknown.

3. *Graphic method.* Figure 32 represents a WARREN TRUSS in which each member is 20 ft. long. Figure 33 is the stress diagram. Using Bow's notation the load line $ALMNOK$ is laid off and the reactions KP and PA determined by symmetry. Starting with joint (1) draw AB and BP which determines point B. AB is 14,400 lb. compression (since it acts towards the joint) and BP is 7200 lb. tension. The polygon for joint (2) is AL, LC, CB, BA, the new point being C. LC is 11,700 lb. compression, CB is 8650 lb. tension. The polygon for joint (3) is PB, BC, CD, DP, the new point being D. CD is 8650 lb. compression, DP is 15,800 lb. tension. The polygon for joint (4) is LM, ME, ED, DC, CL, the new point being E. ME is 17,300 lb. compression, ED is 2900 lb. tension. The polygon for joint (5) is PD, DE, EF, FP, the point being F. EF is 2900 lb. compression, FP is 18,750 lb. tension. Stresses in the remaining members are determined by symmetry.

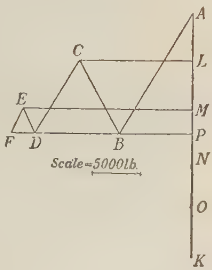

FIG. 33.

11. Cranes and derricks

Simple crane (Fig. 34) consists of a boom AB and tie BC attached to a mast or wall AC, with load supported at B. Stresses in the boom and tie are found by considering the equilibrium of pin B. The force triangle gives the proportion $\dfrac{\text{weight}}{\sin(\alpha+\beta)} = \dfrac{\text{tension in } BC}{\sin\alpha} = \dfrac{\text{compression in } AB}{\sin\beta}$.

Wall crane (Fig. 35) differs from the preceding in that the load is not carried

at B. The boom AD is acted upon by forces at more than two points and stress is no longer simple tension or compression.

Consider the equilibrium of the rigid body AD under the action of four forces: (1) 200 lb. downward at E, (2) 400 lb. downward at D, (3) a force along BC known in direction only, (4) a reaction at A unknown in magnitude and direction. Using two components for the

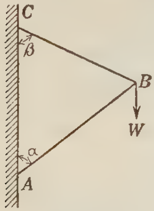

FIG. 34.

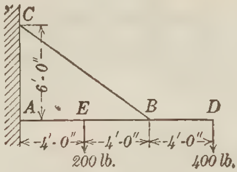

FIG. 35.

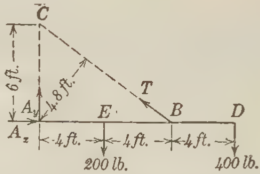

FIG. 36.

unknown forces at A, the problem is to determine the magnitudes of A_x, A_y, T as shown in Fig. 36.

Taking moments about A, $4.8T - 4 \times 200 - 12 \times 400 = 0$, whence $T = 1167$ lb.

Taking moments about B, $-8A_y + 4 \times 200 - 4 \times 400 = 0$, whence $A_y = -100$ lb. (downward).

Taking moments about C, $6A_x - 4 \times 200 - 12 \times 400 = 0$, whence $A_x = 933$ lb.

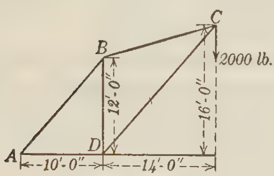

FIG. 37.

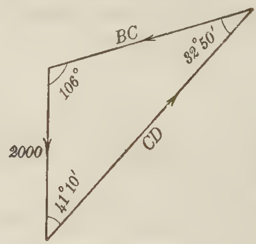

FIG. 38.

Crane with backstay is shown in Fig. 37. The problem is to determine the stresses in the boom CD, tie BC, mast BD, and stay AB. Since all the members are two-force pieces, the stresses are simple tension and compression.

Consider first the pin C for which the force triangle is shown in Fig. 38. The triangle gives $\dfrac{2000}{\sin 32°\,50'} = \dfrac{CD}{\sin 74°} = \dfrac{BC}{\sin 41°\,10'}$, whence $CD = 3550$ lb., $BC = 2430$ lb.

Consider next pin B. From the force triangle $BD = 1280$ lb., $AB = 3040$ lb.

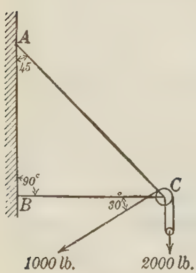

FIG. 39.

Effect of pulleys is illustrated by the crane in Fig. 39. Stresses in the ropes are transferred by means of pulley to pin C, which is in equilibrium under forces shown in Fig. 40.

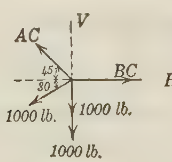

FIG. 40.

Stresses in BC and AC are best determined by taking horizontal and vertical components: H: $BC - 1000 \cos 30° - AC \cos 45° = 0$, V: $AC \sin 45° - 1000 \sin 30° - 2000 = 0$, whence $AC = 3535$ lb., $BC = 3366$ lb.

The frame of Fig. 41 introduces a problem in which the reactions at joints can be determined only by

considering at least two members simultaneously. Complete solution demands the forces on the pins at A, B, C, D, and the supporting force at E (where the frame rests on a smooth floor).

(*a*) Consider the whole frame as a rigid body under the action of (1) 200 lb. downward at F, (2) 300 lb. downward at G, (3) a supporting force acting upward at E, (4) the reaction of the pin at A having components A_x (toward right) and A_y (upward).

Horizontal components show $A_x = 0$.

Taking moments about A: $20E - 200 \times 10 - 300 \times 21 = 0$, whence $E = 415$ lb.

Taking moments about E: $-20A_y + 200 \times 10 - 300 \times 1 = 0$, whence $A_y = 85$ lb.

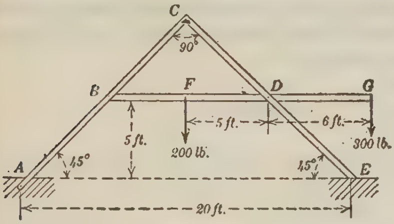

FIG. 41.

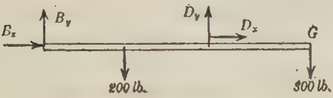

FIG. 42.

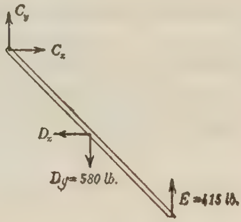

FIG. 43.

(*b*) Consider the member BD in equilibrium under the forces shown in Fig. 42. There are four unknown forces and only three independent equations of equilibrium can be written.

Taking moments about B: $10D_y - 200 \times 5 - 300 \times 16 = 0$, whence $D_y = 580$ lb.

Taking moments about D: $-10B_y + 200 \times 5 - 300 \times 6 = 0$, whence $B_y = -80$ lb. (downward).

Horizontal components give $B_x + D_x = 0$.

(*c*) Consider the member EC in equilibrium under the forces shown in Fig. 43. Observe that the forces exerted by the pin D on member EC are equal and opposite to the forces exerted by the same pin on member BD.

Vertical components give $C_y - 580 + 415 = 0$, whence $C_y = 165$ lb.

Taking moments about C: $-5D_x - 580 \times 5 + 415 \times 10 = 0$, whence $D_x = 250$ lb.

Horizontal components give $C_x - D_x = 0$, whence $C_x = 250$ lb. and, from the equation above, $B_x = -250$ lb. (acts toward the left on BD).

The resulting shear on any pin is found by taking the square root of the sum of the squares of the components. $A = 85$ lb., $B = 262$ lb., $C = 316$ lb., $D = 632$ lb.

Wall crane (Fig. 44) illustrates a problem in space of three dimensions which can be solved by reducing it to problems in two planes.

Plane ABF is perpendicular to wall $ADFE$. The resultant R of the tensions in BE and BD acts along BF. The boom AC is in equilibrium under the action of the forces shown in Fig. 45.

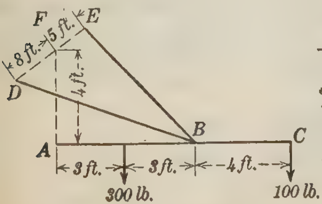

FIG. 44.

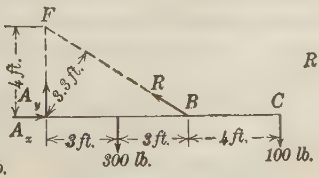

FIG. 45.

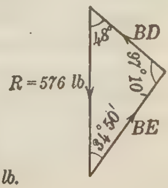

FIG. 46.

Taking moments about A: $3.3R - 300 \times 3 - 100 \times 10 = 0$, whence $R = 576$ lb.
Taking moments about B: $-6A_y + 300 \times 3 - 100 \times 4 = 0$, whence $A_y = 83$ lb.
Taking moments about F: $4A_x - 300 \times 3 - 100 \times 10 = 0$, whence $A_x = 475$ lb.

To find the tensions in BE and BD consider the equilibrium of pin B acted upon by BE, BD, and the boom which exerts a force equal and opposite to R. The force triangle is shown in Fig. 46, from which $BE = 430$ lb., $BD = 335$ lb.

12. Suspended cables

Catenary (Fig. 47) is the curve assumed by a heavy, uniform, flexible, inextensible cord suspended from two points. Let w be the weight per unit length of cord, H be the tension at the lowest point, and $c = H/w$. With axes as shown in Fig. 47 the equation of the catenary is

$$y = \frac{c}{2}(e^{x/c} + e^{-x/c}) = c \cosh x/c.$$

The tension at any point P is given by $T = yw$.

$$\text{Length } LP = \frac{c}{2}(e^{x/c} - e^{-x/c}) = c \sinh x/c.$$

$$\text{Sag } S = \frac{c}{2}(e^{a/c} + e^{-a/c}) - c = \frac{a^2}{2c} \text{ (approximately).}$$

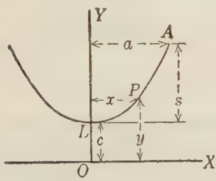

Fig. 47.

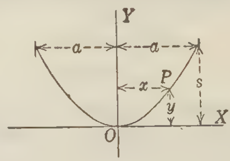

Fig. 48.

Suspension bridge. If the load carried by the cord is distributed uniformly along the horizontal, as in case of a suspension bridge, the curve assumed by the cord is a parabola. Let w be the weight per horizontal unit of length and H be the tension at the lowest point. With axes as shown in Fig. 48 the equation of the curve is $y = wx^2/2H$. If s = sag and $2a$ = span, then $H = wa^2/2s$. The tension at any point P is given by

$$T = \sqrt{H^2 + W^2x^2} = w\sqrt{a^4 + 4s^2x^2}/2s.$$

13. Center of gravity

Definitions. Center of gravity (c. of g.) of a system of particles is the point of application of the resultant of the forces of gravity acting on each particle. For practical engineering purposes these forces of gravity may be regarded as parallel and the center of gravity is given by the formulas of Art. 5. If w_1 is the weight of a particle at (x_1, y_1, z_1), w_2 the weight of a particle at (x_2, y_2, z_2), . . . w_n the weight of a particle at (x_n, y_n, z_n) and c. of g. is at $(\bar{x}, \bar{y}, \bar{z})$, then

$$\bar{x} = \frac{w_1x_1 + w_2x_2 + \ldots + w_nx_n}{w_1 + w_2 + \ldots + w_n} = \frac{\Sigma w_i x_i}{\Sigma w_i},$$

$$\bar{y} = \frac{\Sigma w_i y_i}{\Sigma w_i}, \quad \bar{z} = \frac{\Sigma w_i z_i}{\Sigma w_i}.$$

The center of gravity of any body is the point of application of the resultant of all forces of gravity which act upon every particle of the body. It is given by formulas

$$\bar{x} = \frac{\int x\,dw}{W}, \quad \bar{y} = \frac{\int y\,dw}{W}, \quad \bar{z} = \frac{\int z\,dw}{W},$$

where W = the weight of the body and the limits of the integrals are chosen to cover the space occupied by the body.

If the body is homogeneous, the density D is constant. If V is the volume occupied by the body then $W = DV$ and $dw = D\,dv$ and the formulas become

$$\bar{x} = \frac{\int x\,dv}{V}, \quad \bar{y} = \frac{\int y\,dv}{V}, \quad \bar{z} = \frac{\int z\,dv}{V}.$$

When the body is homogeneous, the center of gravity is called the CENTROID OF THE VOLUME occupied by the body. The CENTROID OF A SURFACE is the limiting position of the center of gravity of a homogeneous thin plate one of whose faces coincides with the surface as its thickness approaches zero. The CENTROID OF A LINE is the limiting position of the center of gravity of a homogeneous thin wire whose axis coincides with the line as the area of its cross-section approaches zero.

Symmetry. The centroid of any geometrical figure lies on any plane or axis of symmetry that the figure may possess.

Table 1. Location of centroids

Centroid of	Drawing	Location of centroid
	General	
1. Straight line.		Midpoint.
2. Circle.		Center.
3. Ellipse (see also (25)).		Center.
4. Sphere.		Center.
5. Ellipsoid (see also (36)).		Center.
6. Any regular figure.		Geometrical center.
7. Plane curve.		$\bar{x} = \frac{\int x\,ds}{\int ds}, \quad \bar{y} = \frac{\int y\,ds}{\int ds}.$

Table 1. Location of centroids—*Continued*

Centroid of	Drawing	Location of centroid
8. Circular arc (see also (16)).		$\bar{x}=\frac{\int x\,ds}{\int ds}=\frac{2\int_0^\alpha r^2\cos\theta\,d\theta}{2\int_0^\alpha r\,d\theta}=\frac{r\sin\alpha}{\alpha}$ $\bar{y}=0.$
9. Any plane area.		$\bar{x}=\frac{\int x\,dA}{\int dA}=\frac{\int\int x\,dx\,dy}{\text{Area}}$ $=\frac{\int\int \rho^2\cos\theta\,d\rho\,d\theta}{\text{Area}}.$ $\bar{y}=\frac{\int y\,dA}{\int dA}=\frac{\int\int y\,dx\,dy}{\text{Area}}$ $=\frac{\int\int \rho^2\sin\theta\,d\rho\,d\theta}{\text{Area}}.$
10. Circular sector (see also (21)).		$\bar{x}=\frac{\int_0^\alpha\int_0^r \rho^2\cos\theta\,d\rho\,d\theta}{\int_0^\alpha\int_0^r \rho\,d\rho\,d\theta}$ $=\frac{\frac{r^3}{3}\int_0^\alpha\cos\theta\,d\theta}{\frac{r^2}{2}\int_0^\alpha d\theta}=\frac{2r\sin\alpha}{3\alpha}.$ $\bar{y}=0.$
11. Surface of revolution. Take X-axis as the axis of revolution and $y=f(x)$ as the generating curve.		$\bar{x}=\frac{\int 2\pi xy\,ds}{\int 2\pi y\,ds}=\frac{\int xy\sqrt{1+\left(\frac{dy}{dx}\right)^2}\,dx}{\int y\sqrt{1+\left(\frac{dy}{dx}\right)^2}\,dx}$ $\bar{y}=0,\qquad \bar{z}=0.$
12. Hemispherical surface. Generating curve: $x^2+y^2=r^2$ $\sqrt{1+\left(\frac{dy}{dx}\right)^2}=\frac{r}{y}.$		$\bar{x}=\frac{\int_0^r x\,dx}{\int_0^r dx}=\frac{r}{2}.$ $\bar{y}=0.\qquad \bar{z}=0.$

Table 1. Location of centroids—*Continued*

Centroid of	Drawing	Location of centroid
13. Solid of revolution. When the X-axis is the axis of revolution and the area revolved is that under the curve $y=f(x)$.	For figure, see (11).	$\bar{x}=\dfrac{\int \pi x y^2 dx}{\int \pi y^2 dx}=\dfrac{\pi \int x y^2 dx}{\text{Volume}}$. $\bar{y}=0$. $\bar{}=0$.
14. Solid hemisphere. Generating curve, $x^2+y^2=r^2$.		$\bar{x}=\dfrac{\pi \int_0^r x(r^2-x^2)dx}{\frac{2}{3}\pi r^3}=\frac{3}{8}r$. $\bar{y}=0$. $\bar{z}=0$.

Lines and curves

Centroid of	Drawing	Location of centroid
15. Three sides of a triangle ABC.		G = centroid. $A'B'C'$ are midpoints. Distance from G to any side $BC = \dfrac{AB+AC}{AB+AC+BC} \times \dfrac{\text{Altitude from } A}{2}$.
16. Circular arc.		On axis of symmetry. $OG = r \times \dfrac{\text{chord } AB}{\text{arc } AB} = \dfrac{r \sin \theta}{\theta}$ (θ = half of central angle in radians). For a quadrant, $OG=\dfrac{4r}{\pi\sqrt{2}}=0.9003r$. For a semicircle, $OG=\dfrac{2r}{\pi}=0.6336r$. Given rise $h(=DC)$ and chord $k(=AB)$ substitute above, $r=\dfrac{k^2+4h^2}{8h}$; $\sin\theta=\dfrac{4hk}{k^2+4h^2}$. For the distance of the centroid from the middle point of the arc, see Table 2.
17. Four sides of a parallelogram.		Intersection of diagonals.

Table 1. Location of centroids—*Continued*

Centroid of	Drawing	Location of centroid
	Surfaces	
18. Triangle.		Intersection of medians.
19. Trapezoid.		On MN joining midpoints of bases. Perpendicular distance from lower base, $d=\frac{h(B+2b)}{3(B+b)}$. To locate graphically, draw $HI=B$ and $JK=b$. Centroid is at intersection of MN and KI.
20. Any quadrilateral $ABDC$		(*a*) Draw diagonal AD. Find centroids of triangles ABD and ACD (18) at E and F. Draw diagonal CB and find centroids of triangles ABC and BCD at G and H. The required centroid is at the intersection of EF and GH.
		(*b*) Draw AC and DB. $F=$ midpoint of DB. Lay off $CH=AE$. The centroid (G) of triangle DHB is the centroid of the quadrilateral and $FG=\frac{1}{3}FH$.
		(*c*) Divide the sides into thirds and construct the parallelogram with sides passing through the third-points as shown. The intersection of the diagonals of this parallelogram is the desired centroid.
21. Sector of a circle.		$OG=\frac{2r\sin\theta}{3\theta}$ $=\frac{2}{3}\text{radius}\times\frac{\text{chord}}{\text{arc}}$ $=\frac{(\text{radius})^2\times\text{chord}}{3\times\text{area}}$ ($\theta=\frac{1}{2}$ angle of sector in radians). See also Table 3.
22. Sector of flat circular ring.		$OG=\frac{2(r_1^3-r_2^3)\sin\theta}{3(r^2{}_1-r_2^2)\theta}$ (θ in radians).

Table 1. Location of centroids—*Continued*

Centroid of	Drawing	Location of centroid
23. Segment of a circle.		$OG=\dfrac{2r\sin^3\theta}{3\theta-\sin\theta\cos\theta}$ (θ in radians). For a semi-circular segment, $OG=\dfrac{4r}{3\pi}=0.4244r$. Given rise h $(=DC)$ and chord $k(=AB)$. $DG=0.4h$ (approximately) when the segment is less than a semi-circle. The exact value lies between $DG=0.4244h$ for a semi-circle ($h=\frac{1}{2}k$) and $DG=0.4000h$ when h is very small.
24. Segment of a parabola.		$OG=\frac{2}{5}OC$. For the half-segment ACO. $Dg=\frac{2}{5}OC$ and $Gg=\frac{3}{8}OA$.
25. Ellipse.		At geometrical center. For semi-ellipse ABB'. $OG=\dfrac{4\,OA}{3\pi}=0.4244\ OA$. For the quarter-ellipse ABO. $Dg=0.4244\ OA$ and $Gg=0.4244\ OB$.
26. Zone of spherical surface.		On axis of zone halfway between bases.
27. Curved surface of cone.		On axis, one third of the distance from the base to the altitude.
28. Slanting surface of a pyramid.		Same as (27).
Solids		
29. Right circular cylinder.		$\bar{x}=\dfrac{ra}{4(2h+a)}=\dfrac{r^2\tan\alpha}{2(2h+a)}$. $\bar{y}=\dfrac{k}{2}=\dfrac{h}{2}+\dfrac{a}{4}+\dfrac{a^2}{16(2h+a)}$.

Table 1. Location of centroids—*Continued*

Centroid of	Drawing	Location of centroid
30. Frustum of a right circular cone.		$OG = \frac{h(R^2+2Rr+3r^2)}{4(R^2+Rr+r^2)}$.
31. Cone.		On axis one-fourth of distance from base to apex.
32. Pyramid.		Same as (31).
33. Segment of sphere		$OG = \frac{3(2r-h)^2}{3r-h}$. $DG = \frac{h(2a^2+h^2)}{2(3a^2+h^2)} = \frac{h(4r-h)}{4(3r-h)}$.
34. Zone of sphere.		$CG = \frac{h(2R^2+4r^2+h^2)}{2(3R^2+3r^2+h^2)}$.
35. Paraboloid.		On axis, one-third of the altitude above the base.
36. Ellipsoid. Lengths of semi-axes $= a, b, c$; equation: $\frac{x^2}{a^2}+\frac{y^2}{b^2}+\frac{z^2}{c^2}=1$.		Centroid of one octant is at $\bar{x} = \frac{3}{8}a$; $\bar{y} = \frac{3}{8}b$; $\bar{z} = \frac{3}{8}c$.

Principle of combination. The centroid of a plane figure composed of two parts lies on the line joining the centroids of the two parts and divides the line in the inverse ratio of the areas of the two parts. A similar statement holds for lines, curved surfaces, and volumes. If the figure is composed of more than two parts, the centroid is found by the formulas (Table 1), in which w_i denotes the area (or length or volume) of one part and (x_i, y_i, z_i) is centroid of this part. The formulas are good for finding the centroid of a figure from which a part has been removed, provided the part removed is given a minus sign.

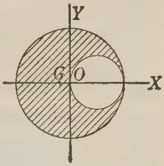

FIG. 49.

Example. Find the centroid of the remainder of a circle of radius r after a circle of radius $r/2$ has been removed (Fig. 49).

From symmetry, $y = 0$. $w_1 = \pi r^2$, $w_2 = -\pi r^2/4$, $x_1 = 0$, $y_1 = 0$, $x_2 = r/2$, $y_2 = 0$.

$$OG = \bar{x} = \frac{\pi r^2 \times 0 - \frac{\pi r^2}{4} \times \frac{r}{2}}{\pi r^2 - \frac{\pi r^2}{4}} = -\frac{r}{6}.$$

14. Moment of inertia

Areas

Moment of inertia of a plane area about an axis is the limit of the sum of the products obtained by multiplying each element of area by the square of its distance from the axis. The moment of inertia is different for different axes. The axis used is indicated by a subscript, thus I_x = moment of inertia about the X-axis.

In Fig. 50,

$$I_x = \int y^2 dA = \int\int y^2 dx\, dy,\ I_y = \int x^2 dA = \int\int x^2 dx\, dy.$$

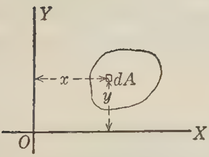

FIG. 50.

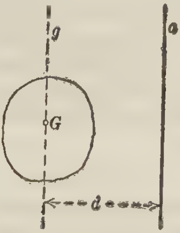

FIG. 51.

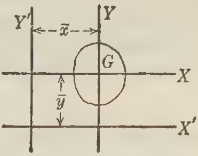

FIG. 52.

The moment of inertia is always positive (never zero). It is called polar if the axis is perpendicular to the plane. I_0 denotes a moment of inertia about an axis through O perpendicular to the XY-plane.

$$I_0 = \int (x^2 + y^2) dA = \int\int (x^2 + y^2) dx\, dy = \int\int \rho^3 d\rho\, d\theta.$$

$$I_0 = I_x + I_y.$$

(Caution. This relation does not hold unless X- and Y-axes are perpendicular.)

Radius of gyration, k is given by $I = Ak^2$, whence $k = \sqrt{I/A}$.

Parallel axes. The moment of inertia of a plane area about any axis is equal to the moment of inertia about the parallel axis through the centroid plus the product of the area and the square of the distance between the axes. Thus (Fig. 51) $I_a = I_g + Ad^2$.

Product of inertia of a plane area with respect to two co-ordinate axes is the limit of the sum of the products obtained by multiplying each element of area by the product of its distances from the co-ordinate axes. Thus $P_{xy} = \int xy\,dA$. The product of inertia may be positive, negative, or zero. It is positive for an area in the first and third quadrants and negative for an area in the second and fourth quadrants.

Parallel axes. The product of inertia of a plane area with respect to a pair of rectangular axes is equal to the product of inertia with respect to a pair of parallel axes through the centroid plus the product of the area and the distances between the axes. Thus (Fig. 52) $P_{x'y'} = P_{xy} + A\bar{x}\bar{y}$.

The product of inertia of an area with respect to a pair of axes one of which is an axis of symmetry is zero.

The moment of inertia of a plane area about different axes lying in the same plane and passing through the same point is calculated by

$$I_l = I_x \cos^2\theta - P_{xy}\sin 2\theta + I_y \sin^2\theta. \quad \text{(Fig. 53.)}$$

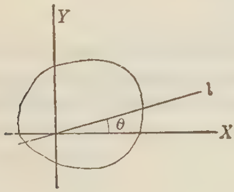

FIG. 53.

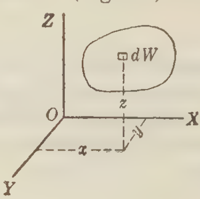

FIG. 54.

Principal axes. Given any plane area and any point in its plane. Consider all axes passing through this point and lying in its plane. Among them there is one about which the moment of inertia of the area is a maximum and one about which it is a minimum. (If the figure is a regular polygon and the point is its center, the moment of inertia is the same for all the axes.) These are called PRINCIPAL AXES. They are perpendicular and the product of inertia with respect to them is zero.

Solid bodies

Moment of inertia of a solid body about an axis is the limit of the sum of the products obtained by multiplying each element of weight by the square of its distance from the axis. (Moment of inertia is also defined by using mass instead of weight.) In Fig. 54

$$I_x = \int (y^2 + z^2)dW, \quad I_y = \int (z^2 + x^2)dW, \quad I_z = \int (x^2 + y^2)dW.$$

Radius of gyration, k, is given by $I = Wk^2$, whence $k = \sqrt{I/W}$.

Parallel axes. The moment of inertia of a solid body about any axis is equal to the moment of inertia about the parallel axis through the center of gravity plus the product of the weight and the square of the distance between the axes.

Product of inertia of a solid body with respect to two co-ordinate planes is the limit of the sum of the products obtained by multiplying each element of weight by the product of its distances from the co-ordinate planes. Thus

$$P_{xy} = \int xy\,dW,\ \ P_{yz} = \int yz\,dW,\ \ P_{zx} = \int zx\,dW.$$

The product of inertia of a solid body with respect to a pair of planes, one of which is a plane of symmetry, is zero.

Principal axes. Given any solid body and any point as origin, among all the axes passing through this point there is one about which the moment of inertia of the body is a maximum and one about which it is a minimum. (For certain regular bodies, if the origin is at the center, the moment of inertia is the same about all axes.) These two axes are perpendicular and, with a third axis perpendicular to each of them, determine a system of co-ordinates for which the three products of inertia vanish. These axes are the PRINCIPAL AXES. If a body has a plane of symmetry, the perpendicular line at any point of the plane is a principal axis for that point. If a body has two planes of symmetry (at right angles to each other) their line of intersection is a principal axis for every point on it. If a body has three planes of symmetry (at right angles to each other) their lines of intersection are the principal axes at the point of intersection.

KINETICS

15. Definitions and laws

Velocity and acceleration. VELOCITY is the rate (with respect to time) of change of position of a point. It is a vector quantity (having magnitude and direction). The magnitude of velocity is SPEED. ACCELERATION is the rate (with respect to time) of change of velocity and is a vector quantity. In considering plane motion of a point two methods of taking components of velocity and acceleration are useful in engineering problems.

(1) *Components parallel to fixed axes.* The position of the point is given by co-ordinates (x, y).

$$v_x = dx/dt, \quad v_y = dy/dt, \quad v = \sqrt{v_x^2 + v_y^2}.$$

$$a_x = dv_x/dt = d^2x/dt^2, \quad a_y = dv_y/dt = d^2y/dt^2, \quad a = \sqrt{a_x^2 + a_y^2}.$$

(2) *Components along the tangent and normal to the path.* The position of a point is given by the distance s from a fixed point A on the path (Fig. 55).

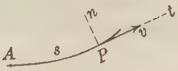

FIG. 55.

$$v_n = 0, \quad v_t = v = ds/dt,$$

$$a_n = v^2/r, \quad a_t = dv/dt = d^2s/dt^2, \quad a = \sqrt{a_n^2 + a_t^2},$$

where r = radius of curvature.

Momentum of a particle is the product of mass and velocity.

Momentum = weight × velocity/g, where g = acceleration due to gravity.

Newton's laws of motion. I. Every body continues in its state of rest, or of uniform motion in a straight line, except in so far as it may be compelled by force to change that state.

II. Change of motion (rate of change of momentum) is proportional to the force applied and takes place in the direction in which the force acts.

III. To every action there is always an equal and contrary reaction; or, the mutual actions of two bodies are always equal and oppositely directed.

16. Motion in a straight line

Uniform motion. Acceleration is zero, velocity, v, is constant. If the position of the moving point is given by its distance, x, from the origin and if $x = x_0$ when $t = t_0$, then

$$x - x_0 = v(t - t_0).$$

Uniformly accelerated motion. Acceleration, a, is constant. If $x = x_0$, $v = v_0$, when $t = t_0$,

$$dv/dt = a, \quad v - v_0 = a(t - t_0), \quad x - x_0 = \tfrac{1}{2}a(t - t_0)^2 + v_0(t - t_0),$$

$$v^2 - v_0^2 = 2a(x - x_0).$$

For bodies moving in a vertical line under the force of gravity, $a = g$. The value of g varies slightly for different positions on the earth's surface. The standard value of g adopted by international agreement is 32.1740 ft./sec.^{2} = 980.665 cm./sec.^{2} The value ordinarily used is g = 32 ft./sec.^{2}

If a body falls from rest

$$v = gt, \quad x = \tfrac{1}{2}gt^2, \quad v^2 = 2gx.$$

If body is projected down with velocity v_0,

$$v = gt + v_0, \qquad x = \tfrac{1}{2}gt^2 + v_0t, \qquad v^2 = 2gx + v_0^2.$$

If body is projected up with velocity v_0,

$$v = v_0 - gt, \qquad x = v_0t - \tfrac{1}{2}gt^2, \qquad v^2 = v_0^2 - 2gx.$$

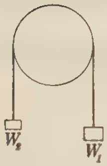

FIG. 56.

Time of ascent $= v_0/g$, height reached $= \tfrac{1}{2}v_0^2/g$.

For motion under gravity on a smooth plane inclined at angle θ to horizontal, $a = g \sin \theta$.

Atwood's* machine consists of two weights attached to the ends of a cord passing over a pulley (Fig. 56). Suppose the inertia of the pulley is neglected (see Art. 19) or that the cord passes over a smooth peg. If $W_1 > W_2$, the acceleration of the weights is given by $a = \dfrac{W_1 - W_2}{W_1 + W_2}g$, and the tension in the cord is $T = \dfrac{2W_1W_2}{W_1 + W_2}$.

General force equation. If a particle of weight W moves along the X-axis under the action of forces whose resultant is F,

$$\frac{W}{g}a = F.$$

This equation is homogeneous in force and acceleration and any system of units may be used. In engineering practice force is measured in pounds and acceleration in feet per second per second. The usual problem in kinetics is one in which F is known and the initial position, x_0, and initial velocity, v_0, are given (at time $t = 0$) and it is desired to determine the subsequent motion. The solution demands integration of a differential equation of the second order for which no general method can be given. Three formulas for acceleration are useful,

$$a = dv/dt = d^2x/dt^2 = v\, dv/dx.$$

Methods of solution are illustrated below.

Example. A 30-ton car moving with a speed of 3 mi./hr. has a spring in the draft rigging requiring a force of 60,000 lb. to compress it 1 in. How much will this spring be compressed when the car strikes a bumping post?

Let $t = 0$ be the instant when the car strikes the post and x = distance moved after $t = 0$; then $x_0 = 0$. $v_0 = 3$ mi./hr. $= 22/5$ ft./sec. The force exerted by the spring is proportional to the compression ($= x$). Hence $F = -720{,}000x$, where F is measured in lb. and x in ft., the minus sign being used because the force on the car is opposite to the direction of motion. The force equation becomes $60{,}000a/32 = -720{,}000x$, whence $v\,dv/dx = -384x$. Integrating, $v^2/2 = -384x^2/2 + C$, where C is a constant to be determined by the initial conditions. $v = 22/5$ when $x = 0$, whence $C = 242/25$. The problem is to determine compression when the car has stopped. Setting $v = 0$, $x = 11\sqrt{96}/480$ ft. $= 2.69$ in.

Resisting medium. The resistance of air depends on the speed of the moving body, being proportional to the square for low speeds. The factor of proportionality depends on the size and shape of the body.

Consider the effect of air resistance on a falling body. The resultant force is $W - k_1v^2$, and the force equation gives $Wa/g = W - k_1v^2$, whence $a = dv/dt = g - kv^2$, where $k = k_1g/W$. To integrate, write $dv/(g - kv^2) = dt$, whence

$$\frac{1}{2\sqrt{g}} \log \left(\frac{\sqrt{g} + \sqrt{k}v}{\sqrt{g} - \sqrt{k}v}\right) = \sqrt{k}\,t + C.$$

The constant of integration, C, is zero if $x = 0$, and $v = 0$ when $t = 0$. Solving for v,

$$v = \frac{dx}{dt} = \frac{\sqrt{g}(e^{\sqrt{kg}\,t} - e^{-\sqrt{kg}\,t})}{\sqrt{k}(e^{\sqrt{kg}\,t} + e^{-\sqrt{kg}\,t})} = \sqrt{\frac{g}{k}}\tanh\sqrt{kg}\,t.$$

Integrating,

$$x = \frac{1}{k}\log\left(\frac{e^{\sqrt{kg}\,t} + e^{-\sqrt{kg}\,t}}{2}\right) = \frac{1}{k}\log\cosh\sqrt{kg}\,t.$$

The expression for acceleration shows that the speed has a limiting value, $v = \sqrt{g/k}$. The relation between v and x is obtained by using $a = v\,dv/dx$ and integrating,

$$\log\left(\frac{g}{g - kv^2}\right) = 2kx \quad \text{or} \quad v^2 = \frac{g}{k}(1 - e^{-2kx}).$$

17. Motion of a particle in a circle

Notation. When a particle moves in a circle of radius r, its position is given by its angular displacement, θ (Fig. 57) from some fixed diameter. Angular velocity, ω, and angular acceleration, α, are given by

$$\omega = \frac{d\theta}{dt}, \quad \alpha = \frac{d\omega}{dt} = \frac{d^2\theta}{dt^2} = \omega\frac{d\omega}{d\theta}.$$

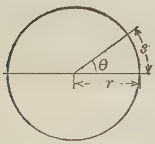

Fig. 57.

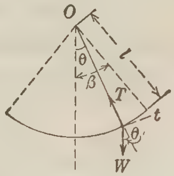

Fig. 58.

Distance, velocity, and acceleration are given by

$$s = r\theta, \quad v = r\omega, \quad a = r\alpha.$$

Simple pendulum consists of a small heavy bob on a light string (Fig. 58). The forces acting on a particle are the weight, W, and tension, T. The resultant force along the tangent $= -W\sin\theta$; the resultant force along the normal $= T - W\cos\theta$. The force equations are $Wa_t/g = -W\sin\theta$, $Wa_n/g = T - W\cos\theta$. Since $a_n = 0$, tension $= W\cos\theta$.

To determine the motion: $a_t/g = l\alpha/g = -\sin\theta$.

The solution of this equation leads to elliptic functions. Approximate solution can be obtained by putting $\sin\theta = \theta$. (Difference between θ and $\sin\theta$ is less than one per cent. if θ is less than 14°.) The differential equation becomes $\omega\,d\omega/d\theta = -g\theta/l$. If the pendulum is at the end of its swing when $t = 0$, then $\theta = \beta$, $\omega = 0$. Integrating, $\omega^2 = g(\beta^2 - \theta^2)/l$; $\omega = \dfrac{d\theta}{dt} = \pm\sqrt{\dfrac{g}{l}}(\beta^2 - \theta^2)$. Integrating, $\theta = \beta\cos\sqrt{\dfrac{g}{l}}t$. Period of oscillation $= 2\pi\sqrt{\dfrac{l}{g}}$.

Conical pendulum (Watt governor) consists of a heavy bob suspended from a fixed point by a light string so that it can be made to rotate about the vertical axis through the fixed point (Fig. 59). If the bob rotates with constant angular velocity, ω, the quantities ϕ, r, h are constants. Since there is no vertical acceleration, $T\cos\phi = W$. The force acting

inward on the bob is $T \sin \phi$. Hence the force equation gives $T \sin \phi = Wa_n/g = Wv^2/gr$, and $\tan \phi = v^2/gr = r\omega^2/g$. Also $h = g/\omega^2$, $T = Wl\omega^2/g$.

Super-elevation of outer rail of a railroad track is determined by the preceding equations where (Fig. 60) r = radius of curvature in ft. and v = speed in ft./sec., $\tan \phi = v^2/gr$. For small angles we may use the sine instead of the tangent and, if h = super-elevation of the outer rail in inches, $h = 56.5v^2/gr$.

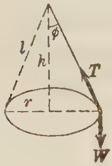

FIG. 59.

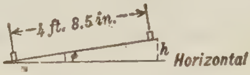

FIG. 60.

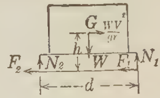

FIG. 61.

Skidding and tipping. Suppose a car (Fig. 61) is taking a curve of radius r ft. at a speed of v ft./sec., G is center of gravity, N_1 is the vertical and F_1 the horizontal pressure on the outer wheel. The problem becomes one of statics by introducing $Wv^2/gr = F_1 + F_2 = F = fW$. If $f < v^2/gr$, the car will skid. Suppose $f > v^2/gr$, then $N_1 = W(\frac{1}{2} + v^2h/dgr)$, $N_2 = W(\frac{1}{2} - v^2h/dgr)$. The critical speed is $v_1 = \sqrt{dgr/2h}$, when the total weight is borne on the outer wheel. If this critical speed is exceeded, the car will tip over.

18. Plane curvilinear motion of a particle

Rectangular force equations. If the co-ordinates of a particle are x, y, components of velocity and acceleration are v_x, v_y, and a_x, a_y (see Art. 15). If the F_x, F_y, are the components of the resultant force on the particle, the force equations are

$$\frac{W}{g}a_x = \frac{W}{g}\frac{d^2x}{dt^2} = \frac{W}{g}\frac{dv_x}{dt} = \frac{W}{g}v_x\frac{dv_x}{dt} = F_x,$$

$$\frac{W}{g}a_y = \frac{W}{g}\frac{d^2y}{dt^2} = \frac{W}{g}\frac{dv_y}{dt} = \frac{W}{g}v_y\frac{dv_y}{dt} = F_y.$$

Normal and tangential force equations. If a particle, P, moves along a curve OP (Fig. 62) and s is the distance along the curve from a fixed point O, then the total velocity is along the tangent and $v_n = 0$. If F_n and F_t are the normal and tangential components of the resultant force on the particle, the force equations are

$$\frac{W}{g}a_n = \frac{Wv^2}{rg} = \frac{W}{rg}\left(\frac{ds}{dt}\right)^2 = F_n, \quad \frac{W}{g}a_t = \frac{W}{g}\frac{d^2s}{dt^2} = \frac{W}{g}\frac{dv}{dt} = \frac{W}{g}v\frac{dv}{ds} = F_t.$$

FIG. 62.

FIG. 63.

Constrained motion occurs when a particle is compelled to follow a given curve. Suppose the particle slides under action of its own weight and friction is neglected. If v_0 = velocity at A (Fig. 63) and v = velocity at B, then $v^2 = v_0^2 + 2gh$. The final speed depends only on the vertical height fallen and not on the shape of the curve or the distance moved. The speed at B' is the same as the speed at B. If P = pressure of the curve on the particle,

Wa_t/g = tangential component of weight, $Wa_n/g = Wv^2/gr = P$ + *normal component of weight;* and $P = Wv^2/gr$ − *normal component af weignt,* where the positive direction of the normal is toward the concave side of the curve.

Example. A particle slides on a smooth vertical circular wire and is just started from rest at the top. Find the pressure on the curve at B and C (Fig. 64).

At B, $v^2 = 2gr$, the normal component of weight = 0, and $P = 2W$. At C, $v^2 = 4gr$, the normal component of weight = − W, and $P = 5W$.

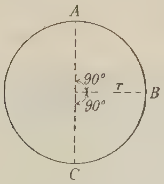

FIG. 64.

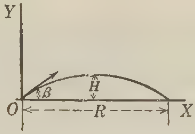

FIG. 65.

Projectile (Fig. 65). If air resistance is neglected, the only force acting (after the initial impulse) is weight. The force equations are $Wa_x/g = 0$, $Wa_y/g = -W$. If, when $t = 0$, $x = 0$, $y = 0$, $v = v_0$, and the angle of the projection with the horizontal $= \beta$, $x = tv_0 \cos \beta$, $y = tv_0 \sin \beta - \frac{1}{2}gt^2$. The trajectory is the parabola $y = x \tan \beta - gx^2/2v_0^2 \cos^2 \beta$. The height, $H = v_0^2 \sin^2 \beta/2g$. The horizontal range $R = v_0^2 \sin 2\beta/g$. The time of flight $T = 2v_0 \sin \beta/g$.

19. Work, energy, power

Work is said to be done on a body by a force when its application point is displaced so that the displacement has a component along the action line of the force. If the force F is constant in magnitude and direction and the displacement in the direction of the force is s, the work done is $F \times s$. The engineering unit of work is the FOOT-POUND (ft.-lb.). If F is constant in direction but variable in magnitude, the *work* $= \int F ds$. If the displacement of the application point is along a curved path, the normal component of force does no work and *work* $= \int F_t ds$. The work done in rotation of a rigid body is $\int G\, d\theta$, where G = the moment of forces (torque) producing the rotation. If G is constant, the work done $= G \times \theta$, where θ is the angle turned through.

Energy is the capacity for doing work which is possessed by a body or system of bodies by virtue of their motion or relative positions. POTENTIAL ENERGY is that due to position. KINETIC ENERGY is that due to motion. For a particle of weight W moving with velocity v,

$$KE = \frac{1}{2}\frac{W}{g}v^2.$$

The fundamental relation between work and kinetic energy is as follows: The work done upon a rigid body by an external system of forces is equal to the change in kinetic energy of the body. If the body is a particle (or body which does not rotate) and if v_0 = initial velocity and v = final velocity, the work done $= W(v^2 - v_0^2)/2g$.

Power is the rate of doing work. The engineering unit is the horsepower (hp.) = 550 ft.-lb./sec. = 33,000 ft.-lb./min.

Work diagram. Let F be the component of force in the direction of motion of the point of application, P, and suppose P moves a distance AD (Fig. 66). Curve BC is obtained by plotting distance as abscissa and force as ordinate. Then the work done by the force is given by

$$\int_{s_1}^{s_2} F\,ds = \text{Area } ABCD.$$

Example is furnished by steam pressure on a piston head. Up to the point of cut-off, K, the pressure is practically constant and equal to that in the boiler, and the work done is represented by the area $ABB'K$ (Fig. 67). After the entering steam **is cut** off, the pressure varies (approximately) inversely as the distance moved from K, and the work done by the expanding steam is represented by the area $KB'CD$. If on the backward stroke the piston head moves against a pressure, the work done by this pressure will be negative and be represented by the area $AHED$, which must be subtracted. The resultant work done on the piston head during one revolution is represented by the area $HBB'CE$. The curve obtained in practice is somewhat irregular (Fig. 68) and the work done is calculated by the measuring **area with a planimeter.**

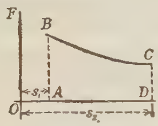

Fig. 66.

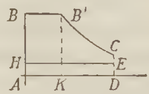

Fig. 67.

Fig. 68.

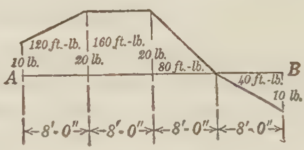

Fig. 69.

Examples of work and energy

1. The work diagram for the resultant of forces moving an 80-lb. weight along a horizontal plane is shown in Fig. 69. If the weight starts from rest at A, find the speed at B.

The work done = 120 + 160 + 80 − 40 = 320 ft.-lb. $KE = \frac{1}{2}\,80v^2/32 = 320$, whence $v = 16$ ft./sec.

2. Water falling from a height of 120 ft. at the rate of 1000 cu. ft./min. drives a turbine directly connected to an electric generator at 120 r.p.m. If the total resisting torque due to friction is 250 lb.-ft., and the water leaves the turbine blades with a velocity of 15 ft./sec find the power developed by the generator.

$1000 \times 120 \times 62.5 = 7{,}500{,}000$ ft.-lb. = work done by force of gravity per min. $.1000 \times 62.5 \times 15 \times 15/2 \times 32 = 219{,}700$ ft.-lb. = KE of water leaving turbine blades per min. $250 \times 120 \times 2\pi = 188{,}500$ ft.-lb. = work used to overcome friction. $7{,}500{,}000 - 219{,}700 - 188{,}500 = 7{,}091{,}800$ ft.-lb./min. = 214 hp. = 160 kw.

Mechanical efficiency of a machine is the ratio of useful work W_u performed by the machine to the work applied W_a to the machine,

$$\text{Efficiency} = \frac{W_u}{W_a}.$$

$W_a - W_u$ = work done in overcoming friction, or loss of energy due to friction.

20. Impulse, momentum, impact

Impulse of a force constant in magnitude and direction is the product of the force and the time during which it acts. If the force is variable in magnitude but constant in direction, impulse $= \int F\,dt$. The unit of impulse is the POUND-SECOND. Impulse is a vector quantity having the same direction as the force, if this direction is constant. If the direction of the force varies, the resultant impulse is the vector sum of the impulses of the components of the force.

Momentum of a particle of weight W moving with velocity v is Wv/g, and is a vector quantity having the same direction as the velocity. The angular momentum of a rigid body rotating about a fixed axis is $I\omega/g$, where I = the moment of inertia about the axis of rotation, and ω = angular velocity. The fundamental relation between impulse and momentum is: The impulse of the resultant force acting upon a particle is equal to the change in momentum of the particle. This is to be understood in the vector sense and may be stated: The component along any line of the impulse of the resultant force acting on a particle is equal to the change in momentum of the particle along that line.

Example. A jet of water strikes a concave vessel with a velocity of 80 ft /sec. and leaves it with a velocity which has the same magnitude but makes an angle of 120° with the original direction. If the diameter of the jet is 1 in. find the force necessary to hold the vessel in position.

The sustaining force F must bisect the acute angle between the lines representing the original and final velocities. Let the line of action of F (Fig. 70) be taken as the X-axis. There is no change in the Y component of momentum. The impulse of the force in the X direction in t sec. = $F \times t$ lb.-sec. The weight of water deflected in t sec. is $W = 80\pi \times 62.5\,t/576$ lb. The component of original momentum in the X direction $= -80\ W \cos 30°/g$ lb.-sec. The component of final momentum in the X direction $= 80\ W \cos 30°/g$ lb.-sec. The change in momentum in the X direction $= 160\ W \cos 30°/g = 5W \cos 30°$ lb.-sec. The fundamental relation gives $F \times t = 5 \times 80\pi \times 62.5 \times \cos 30° \times t/576$, whence $F = 118$ lb. Observe that the sustaining force F does no mechanical work and that the water suffers no loss of kinetic energy.

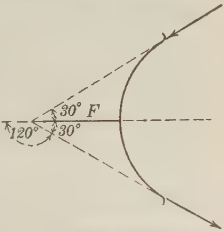

FIG. 70.

Impact occurs when two bodies collide. It is DIRECT when the motion is perpendicular to the striking surfaces; otherwise it is OBLIQUE. It is CENTRAL if the normal to the striking surfaces passes through the centers of gravity of both bodies; otherwise it is ECCENTRIC.

Phenomena of impact. During the impact of two bodies some deformation occurs, beginning at the instant the bodies come in contact and increasing to a maximum. Deformation may be permanent (bodies are inelastic) or the bodies may regain their original shapes (completely, if bodies are perfectly elastic; partially, if bodies are imperfectly elastic). The time of impact of elastic bodies is divided into two parts; first, the period of compression (or deformation) during which the force exerted by one body on the other is the force of compression; second, a period of restitution, with a corresponding force of restitution. There is no period of restitution in the case of inelastic bodies, which will remain in contact with maximum deformation and will move on with a common velocity. The time of impact is very short and it is not possible to determine the force acting at any instant. (But see Example, Art. 16.) The quantity which can be measured is momentum, from which the value of the impulse may be inferred. Ratio, e, of impulse of restitution to

impulse of compression is the COEFFICIENT OF RESTITUTION (or elasticity). For inelastic bodies, $e = 0$; for perfectly elastic bodies, $e = 1$; for imperfectly elastic bodies, $0 < e < 1$. When two bodies collide there is no loss of momentum of the system, but there is loss of kinetic energy except when the bodies are perfectly elastic.

Direct central impact. Let W and W' be the weights of two bodies in collision. Let u = velocity of W before impact, u' = velocity of W' before impact, v = velocity of W after impact, v' = velocity of W' after impact. Then $Wu + W'u' = Wv + W'v'$. If this equation be divided by g we have the statement: The total momentum of the system is the same after as it was before the impact. The coefficient of restitution is, $e = (v' - v)/(u - u')$. The velocities after impact are, $v = \dfrac{Wu + W'u' - W'e(u - u')}{W + W'}$, $v' = \dfrac{Wu + W'u' + We(u - u')}{W + W'}$.

The loss of kinetic energy is expressed by the equation,

$$(\tfrac{1}{2}Wu^2 + \tfrac{1}{2}W'u'^2) - (\tfrac{1}{2}Wv^2 + \tfrac{1}{2}W'v'^2) = \frac{WW'(1 - e^2)(u - u')^2}{2(W + W')}.$$

FIG. 71.

Ballistic pendulum is a device for determining the velocity of a bullet. The bullet is imbedded in soft material so that $e = 0$. Let W (Fig. 71) = weight of bullet, W' = weight of pendulum, k = radius of gyration about the axis of suspension O, u = velocity of bullet to be determined, u' = velocity of pendulum before impact = 0, $v = r\omega$ = velocity of bullet after impact, ω = angular velocity of pendulum after impact, rWu/g = angular momentum of system before impact, $Wr^2\omega/g + W'k^2\omega/g$ = angular momentum of system just after impact. Then $rWu = Wr^2\omega + W'k^2\omega$, and $u = (Wr^2 + W'k^2)\omega/Wr$. If h is the height to which the center of gravity rises, $k^2\omega^2 = 2gh$, and $u = (Wr^2 + W'k^2)\sqrt{2gh}/Wrk$. The quantities on the right-hand side of this equation are easily measured and u is calculated from the equation.

CENTER OF PERCUSSION is the point where the bullet should strike in order that there shall be no horizontal impulse on the axis of rotation. Its distance below P equals $k^2/\bar{r}$.

21. Rotation of a rigid body about a fixed axis

Torque equation. The position of a rigid body rotating about a fixed axis through O (Fig. 72) is given by the angle θ which line OG, fixed in the body, makes with line OX, fixed in space. OG is the line joining O to the center of gravity of the body unless the center of gravity is at O in which case OG is any line fixed in the body.

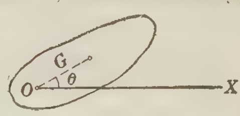

FIG. 72.

ANGULAR VELOCITY, $\omega = d\theta/dt$. ANGULAR ACCELERATION, $\alpha = d\omega/dt = d^2\theta/dt^2 = \omega \; d\omega/d\theta$. TORQUE, G = the sum of the moments of the applied forces about the axis of rotation. I_0 = the moment of inertia of the body about the axis of rotation. The TORQUE EQUATION (equation of angular motion) is, $I_0\alpha/g = G$. If G is constant, α is constant and, if $\theta = \theta_0$, $\omega = \omega_0$, when $t = t_0$, $\omega - \omega_0 = \alpha(t - t_0)$, $\theta - \theta_0 = \tfrac{1}{2}\alpha(t - t_0)^2 + \omega_0(t - t_0)$, $\omega^2 - \omega_0^2 = 2\alpha(\theta - \theta_0)$. If ω is constant, $\alpha = 0$, and $G = 0$. KINETIC ENERGY, $KE = I_0\omega^2/2g$. ANGULAR MOMENTUM, $= I_0\omega/g$. For pressure on axis see Art. 22.

Examples. 1. Atwood's machine (Fig. 73), in the simplest form, consists of two weights W_1 and $W_2 (W_1 > W_2)$ connected by a light cord which passes without slipping over a

pulley of weight W and radius r in the form of a solid cylinder which rotates about a fixed horizontal axis. The problem is to find the acceleration of the system and the tension in the two parts of the cord.

Let a = acceleration of W_1, downward; then a = acceleration of W_2, upward; and $\alpha = a/r$ = angular acceleration of cylinder. For the motion of W_1, $W_1a/g = W_1 - T_1$. For the motion of W_2, $W_2a/g = T_2 - W_2$. For motion of W, $Wr^2\alpha/2g = rT_1 - rT_2$. From these three equations,

$$a = \frac{2(W_1\,W - {}_2)g}{2(W_1 + W_2) + W}, \quad T_1 = \frac{(4W_2 + W)W_1}{2(W_1 + W_2) + W}, \quad T_2 = \frac{(4W_1 + W)W_2}{2(W_1 + W_2) + W}.$$

2. Compound pendulum is any rigid body suspended from a horizontal axis about which it may rotate under the action of its own weight. The forces acting on the body are its weight, acting downward at G (Fig. 74), and the reaction of the axis at O. Let D = distance OG, k_0 = radius of gyration about O. The torque equation gives $Wk_0^2\alpha/g = -WD \sin\theta$, whence $\alpha = -Dg\sin\theta/k_0^2$. This is the equation of a simple pendulum (see Art. 17) of length $l = k_0^2/D$, called the length of the equivalent simple pendulum. The motion of a compound pendulum is the same as the motion of the equivalent simple pendulum.

3. A 2400-lb. wheel with radius of gyration = 4 ft. is making 180 r.p.m. (*a*) How much work must be done to increase the speed to 240 r.p.m? (*b*) If, when making 240 r.p.m., a braking force is applied to the shaft at a distance of 6 in. from the center, find the tangential force if the wheel makes 360 revolutions before stopping.

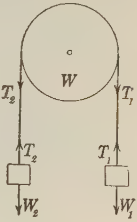

FIG. 73.

180 r.p.m. = 6π rad./sec., 240 r.p.m. = 8π rad./sec.

(*a*) KE (at 180 r.p.m.) = $2400 \times 16 \times 36\pi^2/2 \times 32$ = 213,180 ft.-lb. KE (at 240 r.p.m.) = $2400 \times 16 \times 64\pi^2/2 \times 32$ = 378,990 ft.-lb. Increase in KE = 165,810 ft.-lb. *Ans.*

(*b*) Torque of tangential braking force $F = \frac{1}{2}F$. Work done by torque in 360 revolutions is, $\frac{1}{2}F \times 360 \times 2\pi$ = 378,990, whence F = 335 lb. *Ans.*

4. A punch is required to exert a force of 100,000 lb. through a distance of $\frac{1}{4}$ in. and the work is to be supplied by a flywheel of radius of gyration = 1.5 ft. making 120 r.p.m. Find the weight of the wheel, if the speed is not to be reduced below 100 r.p.m.

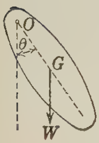

FIG. 74.

ω_1 = 120 r.p.m. = 4π rad./sec., ω_2 = 100 r.p.m. = $\frac{10}{3}\pi$ rad./sec. Work done by punch = 100,000/48 ft.-lb. = reduction in KE of flywheel. Change in $KE = W \times 2.25(\omega_1^2 - \omega_2^2)/64 = W \times 2.25(\omega_1 - \omega_2)(\omega_1 + \omega_2)/64$. Hence

$$\frac{W \times 2.25}{64}(2\pi/3)(22\pi/3) = \frac{100{,}000}{48},$$ whence W = 1230 lb. = minimum weight of flywheel.

22. Plane motion of a rigid body

A rigid body has plane motion if every particle of the body moves in a path that is parallel to a fixed plane. (A book sliding on a table and a rolling wheel are examples. This latter is a case of translation and rotation combined.) The fundamental theorem is that (1) the center of gravity moves as if all the weight were concentrated at that point and all forces applied there; (2) rotation about an axis through the center of gravity takes place as if the center of gravity were fixed in space. The equations for motion of the center of gravity are the equations for motion of a particle. The equation for rotation is the torque equation (see Art. 21). The kinetic energy of a body having plane motion equals the sum of the kinetic energy of translation and the kinetic energy of rotation. If W = weight of body, v = velocity of center of gravity, I = moment of inertia about an axis through the center of gravity, and ω = angular velocity, then

$$KE = Wv^2/2g + I\omega^2/2g.$$

Examples. 1. In Fig. 75 $\tan\beta = \frac{3}{4}$, the wheel weighs 100 lb., diameter = 4 ft., radius of gyration = 1.6 ft. (*a*) Find the acceleration of the center, if the wheel rolls without slipping. (*b*) Find the least coefficient of friction to prevent slipping. (*c*) If the

coefficient of friction = 0.1 find the acceleration of the center and the number of turns made while the center moves 20 ft.

(*a*) The forces acting to move the wheel are $W \sin \beta = 60$ lb. and friction, F. The equation of motion of the center is $100a/32 = 60 - F$. The force acting to turn the wheel is F. The torque equation is $100 \times 1.6 \times 1.6\alpha/32 = 2F$. Since the wheel does not slip, $a = 2\alpha$. Elimination of F gives $a = 11.7$ ft./sec.^{2}

(*b*) Friction = coefficient of friction × normal pressure, or $F = fW \cos \beta = f \times 80$. From the equation above $F = 23.4$ lb., whence $f = 0.29$.

(*c*) The relation between a and α is not known when the wheel slips. $F = 80 \times 0.1 = 8$ lb. The equation of motion of the center is $100a/32 = 60 - 8 = 52$, whence $a = 16.6$ ft./sec.^{2} Distance moved by center, $x = 8.3t^2$. Time to move 20 ft. is given by $t^2 = 20/8.3$. Torque equation is $100 \times 1.6 \times 1.6\alpha/32 = 2 \times 8$, whence $\alpha = 2$ rad./sec.^{2} The angle turned through, $\theta = t^2 = 20/8.3 = 2.41$ rad. $= 0.38$ revolution.

2. In Fig. 76 A is a solid cylinder of weight W about which is wrapped a light cord. B is a smooth peg, C is a weight W' which slides without friction on a horizontal plane. Find the acceleration of A and of C.

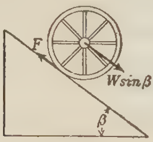

Fig. 75.

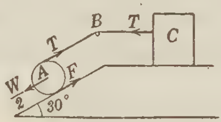

Fig. 76.

Fig. 77.

As A rolls down the plane, the cord is wrapped about it and the distance s' moved by W' equals twice the distance s moved by the center of W. Then $s' = 2s$ and $a' = 2a$. The equation of motion of the center of A is $Wa/g = W/2 - T - F$. The torque equation is $Wr^2\alpha/2g = r(F - T)$. Assuming the cylinder does not slip, $r\alpha = a$. The equation of motion of C is $W'a'/g = T$. Elimination of T and F gives $a = Wg/(3W + 8W')$.

3. A straight rod, 6 ft. long, of uniform section and weighing 60 lb., revolves in a horizontal plane about a vertical axis through its middle point O at a speed of 500 r.p.m. (*a*) Find the torque necessary to impart the speed of 500 r.p.m. in 20 sec.

(*b*) Find the tension due to centrifugal force at the middle section of the rod and at a section 2 ft. from O. (Fig. 77.)

To find the torque, $I\alpha/g = G$, where $I = \frac{60}{3} \times 9 = 180$; $\alpha = (500 \times 2\pi)/(60 \times 20) = 2.62$, $G = 14.6$ lb.-ft. To find the tension at the mid-section consider the motion of half the rod. Its center of gravity revolves in a circle of radius 1.5 ft. with a speed $v = 500 \times 2\pi \times 1.5/60$ ft. sec. The normal force (tension at mid-section) is given by $T = 30v^2/1.5g = 3850$ lb. To find the tension at a section 2 ft. from O, consider the motion of part A, the weight of which is 10 lb. and whose center of gravity moves in a circle of radius 2.5 ft. with a speed $v = 500 \times 2\pi \times 2.5/60$ ft. sec. The normal force on A is $T = 10v^2/2.5g = 2140$ lb.

Pressure on axis of rotation is found by the method illustrated in problem 4.

4. A straight rod of uniform section and material, 4 ft. long and weighing 40 lb. is suspended from a horizontal axis through a point O, 1 ft. from the upper end (Fig. 78). A force F of 8 lb. is applied perpendicular to the rod. Find the pressure on axis O if F is applied at the lower end; at the upper end. Where must F be applied if there is no pressure on the axis perpendicular to the rod?

Fig. 78.

At the instant F is applied the angular velocity of the rod is zero and the pressure on the axis in the direction of the rod is the weight = 40 lb. When the angular velocity = ω, the pressure on the axis in the direction of the rod is found by the method of the preceding problem.

To find the pressure on the axis perpendicular to the rod, find the angular acceleration α. $I\alpha/g$ = moment of F. $I = \frac{280}{3}$ lb.-ft.^{2}

When F is applied at the lower end, $\alpha = \frac{288}{35} = 8.2$ rad./sec.^{2} The center of gravity moves in a circle of radius, = 1 ft. and $a = 8.2$ ft./sec.^{2} Let P = the pressure of the axis on the rod in the same direction as F. The equation of motion of the center of gravity is $Wa/g = F + P$, whence $P = 2.3$ lb.

When F is applied at upper end its moment $= -8$ lb.-ft. and $\alpha = -\frac{96}{35} = -2.7$ rad./sec^2. $P = -11.4$ lb. (opposite to direction of F).

To find the center of percussion (point where F must be applied to give no pressure on the axis perpendicular to the rod) assume x = distance from O of point of application.

Then $280\alpha/3 \times 32 = 8x$, and $a = \alpha = 96x/35$. $^{40}\!/_{32} \times {}^{96}\!/_{35} \times x = 8 + 0$, whence $x = {}^{7}\!/_{3}$ ft. below 0.

23. Friction

Sliding friction is resistance to motion that is developed when one body slides, or tends to slide, over the surface of another. STATIC FRICTION is that which opposes any tendency to move on the part of two bodies in contact, that are relatively at rest. KINETIC FRICTION occurs when the bodies are in motion relative to each other.

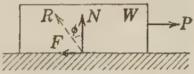

FIG. 79.

Coefficient of sliding friction. Weight W (Fig. 79) is pulled along a horizontal plane by the horizontal force P. The reaction of the plane is R, having a normal (vertical) component N and a tangential (horizontal) component F = friction. The ratio $f = F/N = \tan\phi$ is the COEFFICIENT OF SLIDING FRICTION and ϕ is the ANGLE OF FRICTION.

If P is not large enough to move W the friction is static and $F = P$. As P increases F will increase until W is just about to move. LIMITING FRICTION is the maximum value of static friction. The COEFFICIENT OF STATIC FRICTION is the ratio of the limiting friction to the normal pressure and is usually larger than the coefficient of sliding friction.

Suppose the plane on which W rests is inclined to the horizontal at angle θ. If $\theta < \phi$, W will not slide down; if $\theta > \phi$, W will slide down.

Laws of friction for surfaces which are dry, or nearly so, are

1. Friction between two given bodies is directly proportional to the pressure; the coefficient of friction is constant for all pressures.

2. The coefficient and amount of friction for given pressures is independent of the area of contact.

3. The coefficient of friction is independent of the relative velocity, although static friction is greater than kinetic friction.

The preceding laws are only approximately true. The coefficient of friction is slightly greater for small pressures upon large areas than for great pressures on small areas. The coefficient of friction decreases as the speed increases.

The following table of coefficients of friction (Table 5) is from experiments by Morin about 1830.

Friction of lubricated surfaces does not follow the laws for dry surfaces, but depends on the viscosity and thickness of the lubricant and the form of the surfaces in contact. The LAWS given by Goodman are

1. The coefficient of friction of well-lubricated surfaces is from $1/6$ to $1/10$ that of dry or poorly-lubricated surfaces.

2. The coefficient of friction for moderate pressures and speeds varies approximately inversely as the normal pressure; frictional resistance varies as the area of contact, normal pressure remaining the same.

3. For low speeds the coefficient of friction is abnormally high but as the speed of the rubbing surfaces increases from about 10 to 100 ft. min. the coefficient of friction diminishes and again rises when that speed is exceeded, varying approximately as the square root of the speed.

4. The coefficient of friction varies approximately inversely as the temperature.

Rolling friction is the resistance to motion developed when one body rolls over the surface of another, and depends on the hardness of the surfaces in contact and the radius of the rolling surface. The theory is based on the idea that surfaces are slightly deformed at the place of contact and that the effect of rolling friction is the same as if the surfaces were not deformed and the rolling body

Table 5. Coefficients of friction.

Material	Condition of surface	f	ϕ
Brass on oak	Dry	0.62	31° 48′

passed constantly over a small obstruction. Let P (Fig. 80) be the horizontal force required to overcome the small obstruction B. Then $hP = aW$, and, since h is nearly equal to r, $P = aW/r$ (approximately). COEFFICIENT OF ROLLING FRICTION is a. It is a linear distance and is usually given in inches. For iron railroad wheels a varies from 0.0196 to 0.0216 in.

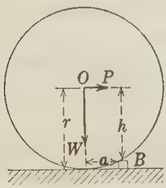

FIG. 80.

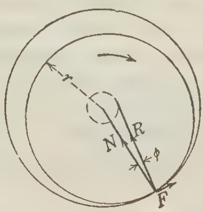

FIG. 81.

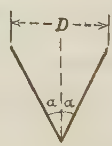

FIG. 82.

Axle friction. If a cylindrical axle fits loosely in a cylindrical bearing, the bearing surface will be a narrow strip or element. If the axle turns in the direction of the arrow (Fig. 81) it will rise in the bearing to some position as

shown. F is friction, N normal pressure, and $R = \sqrt{F^2 + N^2}$ = resultant pressure of bearing on axle. Let f = coefficient and ϕ = angle of friction between the surfaces. $F = N \tan \phi = R \sin \phi$. The FRICTION CIRCLE is the circle drawn about O and tangent to the line of action of R. Its radius is $\rho = r \sin \phi$ and the moment of F is $Fr = R\rho$. Angle ϕ is usually small and $\tan \phi$ is used instead of $\sin \phi$, giving $F = R \tan \phi = fR$, $\rho = r \tan \phi = fr$.

The work done by friction during each revolution of the shaft is $2\pi Fr = 2\pi R\rho$. The power necessary to overcome friction when the axle makes n revolutions per sec. is,

$$Power = 2n\pi Fr = 2n\pi R\rho = 2n\pi rfR \text{ ft.-lb./sec.}$$

Pivot friction occurs when the end of a vertical (or inclined) shaft rests in a bearing. If the end of the shaft is flat and the bearing pressure is constant over the surfaces in contact, the work necessary to overcome friction during one revolution is $2\pi fDT/3$, where f = coefficient of friction, D = diameter of shaft, T = total thrust on bearing. If the end of the shaft is conical (Fig. 82), the work necessary to overcome friction during one revolution = $2\pi fDT/3 \sin \alpha$.

Belt friction. When power is transmitted by a belt over a pulley, the tension T_1 on one side is greater than the tension T_2 on the other side of the pulley. The relation between T_1 and T_2 is $\dfrac{T_1 - Wv^2/g}{T_2 - Wv^2/g} = e^{f\alpha}$, where W = weight of belt per linear ft., v = speed of belt in ft./sec., f = coefficient of friction between belt and pulley, α = angle of contact between belt and pulley, e = base of natural logarithms = 2.718+. For small speeds the centrifugal force (Wv^2/g) may be neglected and $T_1/T_2 = e^{f\alpha}$.

Power transmitted is given by

$$\text{Power} = (T_1 - T_2)v \text{ ft.-lb./sec.} = (T_1 - T_2)v/550 \text{ hp.}$$

SECTION 27

APPLIED MECHANICS

STRENGTH OF MATERIALS. HYDRAULICS

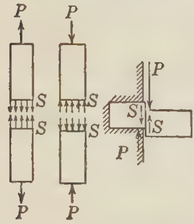
BY

CHARLES T. PORTER

CHIEF ENGINEER, HUFF DALAND AIRPLANES, INC.

1. Simple stresses. Elasticity. Deformation

Definitions. STRESS is internal force between molecules; it resists change in form and rupture when a body is subject to external forces. Internal stresses hold external forces in equilibrium and in their action are equal and opposite to the action of these forces. UNIT STRESS (intensity) is the total uniform stress in a body divided by the area over which the stress is distributed. It is expressed in lb. per sq. in., tons per sq. ft., kg. per sq. cm., etc. TENSION (Fig. 1, a) is stress tending to keep two adjacent planes in a body from being pulled apart. It resists increase in length of the body in the direction of applied forces. External forces act away from, and internal stresses toward, any given section area normal to the direction of stress. COMPRESSION (Fig. 1, b) is stress resisting decrease in the distance between two adjacent planes in a body. External forces act toward, and stresses away from any given section. SHEAR (Fig. 1, c) is stress tending to keep two adjacent planes in a body from sliding on each other under the action of two equal and opposite external forces which are slightly separated; the action is similar to a pair of shears. Shearing stress is assumed equally distributed over the resisting area unless otherwise noted. Shearing stresses always occur in pairs and are of equal magnitude on all faces of a unit cube (Fig. 2). If vertical stresses S_v resist external shearing forces a couple is necessary to prevent rotation. This is supplied by the horizontal shearing stresses S_v'.



(a) (b) (c)

a, Tension. *b*, Compression. *c*, Shear.

FIG. 1.—Simple stresses.

The two pairs of shearing stresses in any plane may be combined into two equal and opposite tensile stresses tending to elongate one diagonal or into compressive stresses tending to shorten the other diagonal. The resultant action tends to give the unit cube an angular deformation. (Fig. 3.) This diagonal tension is important in design of concrete structures.

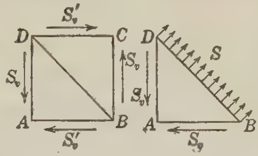


FIG. 2.

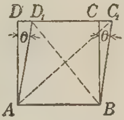

FIG. 3.

Shearing stresses in tension and compression. When a bar is subjected to simple tension or compression, shearing forces occur on diagonal planes. In Fig. 4 consider a plane making angle θ with the axis of a bar whose area at right-angles to P is A. Stress on this plane can be resolved into compressive stress normal to the plane and shearing stress along the plane. Value of shearing stress $S_v = P(\sin 2\theta)/2A$ which has a maximum value of $P/2A$ when $\theta = 45$ deg. Brittle materials under compressive loads fail by shearing along diagonal planes.

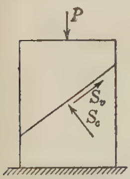

FIG. 4.—Shear due to compression.

Simple-axial stresses occur when resultant forces act along the axis of a body of symmetrical form and the stresses are equally distributed over section area. Axial tension and compression are common in engineering structures. Let P = load or one of a pair of forces producing tension, compression, or shear, A = area over which stress is distributed, and S = unit stress. Then $P = SA$.

Deformation or strain is change in form produced in a body by the action of external forces. Deformations are longitudinal, accompanied by stresses of tension or compression, or angular, produced by shearing forces. Stress resists deformation; the two occur simultaneously under the action of external force.

Poisson's ratio. When longitudinal deformation takes place in body, lateral deformation also occurs. If a block is shortened an amount d under a compressive load, it will increase in width an amount d_1 (Fig. 5). The corresponding unit deformations are $e = d/l$ and $e_1 = d_1/l_1$ and the ratio e_1/e is defined as Poisson's ratio m. Some values of m are: brass, 0.333; cast iron, 0.27; wrought iron, 0.278; steel, 0.303; concrete, 0.10 to 0.25.

Hooke's law states that, when the unit stress in a body does not exceed a certain limit, which varies with the nature of the material, stress bears a constant ratio to deformation or strain.

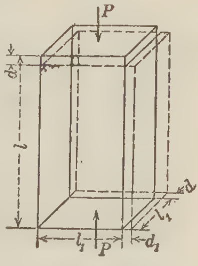

FIG. 5.

Elastic limit. Experiments show that within certain limits a body deformed under load will return to the original form upon removal of the load. Beyond this limit deformation increases more rapidly than the corresponding stress and the body, upon removal of load, will not return to the original form but will have permanent deformation, called SET. The maximum unit stress at which stress and deformation are directly proportional and which will cause no permanent set is called THE ELASTIC LIMIT.

Modulus of elasticity is the ratio of unit stress to unit deformation within the elastic limit. Let E = modulus of elasticity, then $E = S/e = Sl/d = Pl/Ad$. Modulus of elasticity is sometimes called YOUNG'S MODULUS or COEFFICIENT OF ELASTICITY. It is measure of the stiffness of a body. The reciprocal of E is a measure of relative deformation of different materials under the same unit stress.

Example. Average values of E for steel, cast iron, and timber are 30,000,000, 12,000,000 and 1,500,000 lb. per sq. in., respectively. Rods of these materials 10 ft. long under unit tension of 1000 lb. per sq. in. will elongate $d = 1000 \times 120/E = 0.004$, 0.01, and 0.08 in., respectively. Relative deformations are 1, 2.5, 20.

Stress-deformation diagram shows graphically the behavior of material under stress from no-load to rupture.

A bar is placed in a testing machine, load applied, and deformations read with strain gage or extensiometer. Unit deformation is plotted as abscissa and unit stress as ordinate. Figure 6 shows the relative behavior under tensile stress of three materials of construction. The curve is a straight line from the origin to the *elastic limit*, marked (a). The tangent to this curve is $S/e = E$. After passing the elastic limit e increases faster than S until, in the case of medium steel, the curve becomes horizontal at (b), the YIELD POINT. This point is defined as the unit stress at which deformation increases without increase in load and is readily determined by a testing machine as the point where the beam drops. At this point also a hard mill scale begins to peel off the specimen. The yield point is generally known as

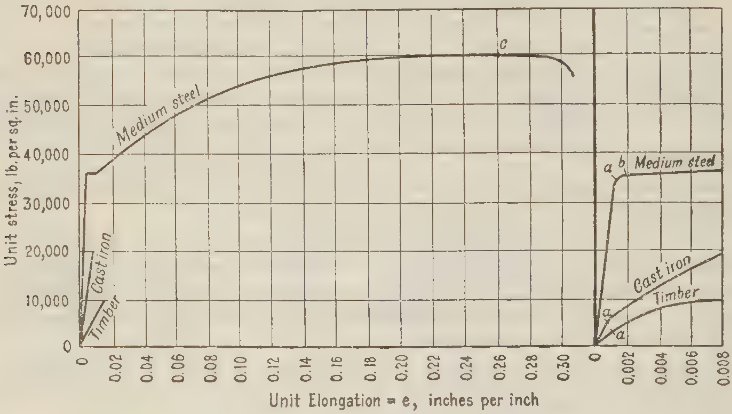

FIG. 6.—Stress-deformation diagram.

the COMMERCIAL ELASTIC LIMIT in commercial testing. The true elastic limit is often several thousand pounds below the yield point and is determined by plotting the stress-deformation diagram and noting the point of departure from a straight line. Many materials have no yield point or clearly defined elastic limit. For these cases Johnson has defined an APPARENT ELASTIC LIMIT as the unit stress at which the slope of the curve is 50 per cent. greater than at the origin.

Shearing modulus of elasticity or COEFFICIENT OF RIGIDITY is $G = S_v/\theta$, in which S_v = unit shearing stress and θ = angle in radians, Fig. 3. Unit of G is lb. per sq. in.

Elongation of a bar due to its own weight is one-half that produced by an equal weight suspended from the lower end.

Uniform bar of weight W lb. and length l in. is suspended vertically and carries a load P lb. at the lower end. Total elongation $d = (P + W/2)l/AE$ in.

Stress due to temperature charge. If a bar is free to expand and contract, its change in length for a temperature change t is $d = ntl$, in which n = the coefficient of linear expansion per degree of temperature. If the bar is rigidly fixed so that change in length is prevented, the resulting unit stress is the same as that required to cause deformation d. Hence $d = Sl/E = ntl$ or $S = ntE$ lb. per sq. in.

Example. Railroad rails 30 ft. long are laid end to end at temperature 50° F. At 90° F. the unit compressive stress is $S = 0.0000065 \times 40 \times 30{,}000{,}000 = 7800$ lb. per sq. in. (For values of coefficient of expansion, see Sec. 25, Art. 6.)

Stresses in compound bodies or bodies of two or more materials are directly proportional to the respective values of E. Let a short block carrying a compressive load P be composed of two materials, the section areas being A_1, A_2 and moduli of elasticity, unit stresses, and loads being E_1, E_2; S_1, S_2; and P_1, P_2, respectively. Then, since deformation of each material is the same, $d = P_1l/A_1E_1 = P_2l/A_2E_2$. Also $P_1 + P_2 = P$. Hence $P = P_1(A_1E_1 + A_2E_2)/A_1E_1 = P_2(A_1E_1 + A_2E_2)/A_2E_2$ and $S_1 = PE_1/(A_1E_1 + A_2E_2)$; $S_2 = PE_2/(A_1E_1 + A_2E_2)$. $S_1/S_2 = E_1/E_2$.

Example. If a block is a 6 × 4-in. wooden stick with two steel plates 6 in. by ¼ in. on the sides, and the total load is 84,000 lb., finding E from Table 1, stresses in wood and steel are 1000 and 20,000 lb. per sq. in., respectively.

Resilience is potential energy stored in a body under stress when the latter does not exceed the elastic limit and equals the work done in producing deformation in the body. For axial stress, if V = volume of the body, *resilience = work done = average force × deformation* $= Pd/2 = \frac{1}{2}P \times Sl/E = VS^2/2E$, in.-lb. per cu. in.

Modulus of resilience, R, is the elastic energy stored in a body per cu. in. at the elastic limit. $R = S_1{}^2/2E$ in which S_1 = elastic limit of material. Values of R for cast iron, structural steel, and tempered spring steel, are 1.04, 15, and 205 in.-lb., respectively. Cast iron is a poor material in which to store elastic energy while spring steel is excellent.

2. Stresses beyond the elastic limit

When stressed beyond the elastic limit, ductile materials such as soft steel become semi-plastic. At the yield point a flow of material occurs, deformation increasing without increase in load, accompanied by peeling off of hard scale. Beyond the yield point stress again increases and the material elongates rapidly, being in semi-plastic, semi-elastic condition. Just preceding rupture the bar necks down as shown by Fig. 7, rupture finally occurring at the contracted section.

Ultimate strength is maximum load divided by the *original* area. It occurs before rupture, point c, Fig. 6.

(*a*) (*b*)
a, Hard material
b, Ductile material.
FIG. 7.—Fractures in tension.

Ultimate elongation is expressed as 100 × *total elongation divided by original length.* It is measure of DUCTILITY or the ability of material to withstand shock and absorb energy without rupture. It varies from approximately zero for hard brittle materials to 30 per cent. or more for rivet steel. It varies with length of specimen hence the latter is always specified, *i.e.*, for rivets and structural steel, minimum unit elongation in 8 in. is specified as 1500 ÷ *ultimate strength.*

Reduction in area is $(A - A_1)/A$ where A = original area and A_1 = area of reduced section or neck. This factor is also a measure of ductility.

Permanent deformation occurs when metals are stressed beyond the elastic limit, Fig. 8. The effect is increase in ultimate strength, increase in elastic limit, increase in hardness, and decrease in ductility. Rolling, drawing, and forging of steel greatly increase its ultimate strength and elastic limit but cause marked decrease in elongation and reduction of area.

Annealing an overstrained bar by heating to 1400° F., and allowing to cool for several days, restores the original properties.

Failure under compression. Direct compressive stresses exist only in short blocks whose length in the direction of stress is less than 10 × *least diameter*. Longer blocks are classified as columns and fail by bending as well as by compression.

Soft ductile materials have no ultimate compressive strength since such material, when stressed beyond the yield point, spreads out indefinitely, Fig. 9. The value is generally assumed the same as that for tension although the term has no real significance. Hard brittle materials fail in compression by shearing along diagonal planes, the more brittle the material, the less the angle the plane makes with the vertical. ULTIMATE STRENGTH is a function of the shearing strength and coefficient of friction. Figure 9 shows failure of common materials of construction under compression.

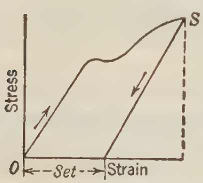

FIG. 8.

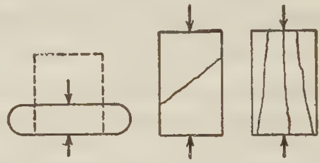

Wrought iron. Cast iron. Brick.

FIG. 9.—Fractures in compression.

Repeated stresses may cause rupture at a stress considerably below the elastic limit. The greater the range of stress, the less the stress required for rupture. Bars stressed repeatedly from zero to the elastic limit require an enormous number of applications of load to cause rupture. If stress alternates from tension to compression the bar will rupture after a large number of applications at little more than half the elastic limit.

3. Properties of materials

Average properties of materials are given in Table I. Strength of steel varies with the chemical composition, heat treatment and mechanical working.

Table 1. Average properties of materials

Material	Weight per cubic foot	Elastic limit, pounds per square inch	Ultimate strength, pounds per square inch			Modulus of rupture, pounds per square inch	Modulus of elasticity, ten., comp., shear, 1000 lb. per square inch	
			Tension	Comp.	Shear			
Wrought iron..........	480	28,000	50,000	50,000	40,000	....	28,000	12,800
Cast iron..............	450	6,000*t*	20,000	90,000	18,000	35,000	15,000	6,500
Malleable cast iron.....	....	20,000*c*	38,000	......	......	....	......	......
Steel, soft..............	490	25,000	50,000	50,000	38,000	....	30,000	13,000

a With grain. *b* Across grain. *c* Compression. *t* Tension.

ULTIMATE TENSILE STRENGTH varies from 45,000 to over 200,000 lb. per sq. in. HARDNESS increases and DUCTILITY decreases as tensile strength increases. Timber values are subject to wide variation, depending on the kind of wood, closeness of grain, moisture content, and homogeneity of the specimen. More detailed data are given in Arts. 6, 7, 15, 16.

Working stress is the safe unit stress allowable in material as used in design of members of a structure. It should be well below the elastic limit and is generally fixed by specification.

Working stresses in accordance with building laws of NEW YORK and CHICAGO are given in Tables 2 and 3.

Table 2. Working stresses, tension and compression, in accordance with building laws, New York and Chicago (1913)

Material	New York		Chicago	
	Pounds per square inch			
	Tension	Compression	Tension	Compression
Rolled steel, mild	16,000	16,000	14,000	14,000
Rolled steel, medium	16,000	16,000	14,000	14,000

Factor of safety is the ratio of ultimate strength to working stress or ratio of load to cause rupture to existing load on the structure. A factor of safety is necessary to guard against possible defects in material and to allow for unforeseen increase in stress. It depends for its value on the degree of certainty with which the ultimate strength is known and on similar knowledge in respect to applied loads.

Steel and iron have ultimate strengths that are nearly constant for given composition and treatment while the strength of wood varies widely, hence the factor of safety for steel is lower than that for timber. A steady load permits a lower factor than variable load or shock. Average values of factor of safety, according to *Merriman*, are given in Table 4.

Suddenly-applied loads cause a unit stress and deformation that is twice that caused by a static load of the same value.

Table 3. Working stresses, flexure and shear

Material	New York		Chicago	
	Pounds per square inch			
	Extreme fiber stress, bending	Shear	Extreme fiber stress, bending	Shear

Concrete (Rosedale) 1 : 2 : 4	16	......	......	......

C, compression. *T*, tension.

Loads applied gradually, so that stress increases gradually from 0 to final value S are equivalent to static loads and $S = P/A$. When the load is suddenly applied so that the full load P acts through the whole deformation d_1 the work done is Pd_1. Had a load P_1 been applied gradually to produce the same deformation d_1, the work done would have been $P_1/2 \times d_1$. Hence $P \times d_1 = P_1/2 \times d_1$ or $P_1 = 2P$ and $d_1 = 2d$.

Table 4. Average values of factor of safety

Material	Steady stress	Variable stress	Shocks
Cast iron	6	10	20
Wrought iron	4	6	10
Structural steel	4	6	10
Hard steel	5	8	15
Timber	8	10	15
Brick and stone	15	25	40

Impact factor or coefficient of impact is the factor introduced to allow for the effect of sudden application of load. In designing structural members, static or dead-load stresses and live-load stresses are computed separately. The latter are found in the ordinary manner and then increased an amount iS in which i is the impact factor and S is stress due to live load treated as static load.

For suddenly applied loads as in hoisting machinery i = unity. For more gradually applied loads as in case of cranes or trains entering a bridge, i is less than unity. For railroad bridges the common value for impact factor is $i = 300/(L + 300)$ in which L is the loaded length in feet that produces maximum stress in the member. For highway bridges American Bridge Co. specifies $i = 0.25$. In many cases in design the impact factor is allowed for in the specified value of the working stress or in the factor of safety.

Stresses due to impact are those caused by a moving load striking a body. Let load P, moving horizontally with velocity V strike the end of a horizontal bar. The kinetic energy of the moving load $= PV^2/2g$ (or Ph, if h is the vertical distance through which the load must fall to acquire the velocity V). This kinetic energy goes into work of deformation of the bar, hence, if $d_1 =$ deformation, and $P_1 =$ static load required to produce this deformation, $Ph = P_1/2 \times d_1$. Also if $d =$ deformation produced by P acting as a static load then $d_1/d = P_1/P$. Solving these equations for P_1 there results $P_1 = P(2h/d)^{1/2}$ and $d_1 = (2hd)^{1/2}$. The corresponding unit stresses are $S_1 = S(2h/d)^{1/2}$.

If the bar be vertical and the moving load fall upon it from height h, the work done is $P(h + d_1)$ and $S_1 = S + S(1 + 2h/d)^{1/2}$; $d_1 = d + d(1 + 2h/d)^{1/2}$ in which $S =$ static stress due to load P and $S_1 =$ impact stress. These values apply only when the elastic limit of the material is not exceeded. Results are a little too large for heavy bars since the inertia of the bar has been neglected. Actually part of the energy is used to overcome inertia of the molecules and is dissipated in heat. For light bars the values are correct.

Example. A 100-lb. weight drops 6 in. and strikes the end of a vertical steel rod 2 in. $\times$ 2 in. $\times$ 10 in. Impact stress $S_1 = 25 + 25(1 + 12 \times 30{,}000{,}000/25 \times 10)^{1/2} = 31{,}275$ lb. per sq. in. Static stress is 25 lb. per sq. in.

Rupture by impact may be caused by light loads moving with considerable velocity. The preceding formulas do not apply. Experiments show that the work necessary to cause rupture is about 30 per cent. greater if it is the result of impact than if done by a static load.

4. Riveted joints

Riveted joints fail by tearing the plate between rivet holes, by shearing rivets or by crushing the plate and rivets where they mutually bear on each other.

Efficiency of a joint is the ratio of its strength to that of a solid unriveted plate.

Let $P =$ load in lb. on each repeating section, $p =$ pitch of rivets or length of repeating section, $t =$ thickness of plate, $d =$ diameter of rivet, $S_t =$ unit tensile stress in plate, $S_c =$ unit compressive stress on rivet, $S_s =$ unit shearing stress on rivet. Let there be n rivets in each repeating section and m rivet sections in shear. The loads to rupture the joint by tension, compression, and shear are respectively $P_t = (p - d)tS_t$; $P_c = ndtS_c$, and $P_s = \frac{m\pi d^2}{4} S_s$. Corresponding efficiencies are found by dividing the above values by the strength of the unriveted plate, $P = ptS_t$. For MAXIMUM EFFICIENCY design the pitch so that the efficiency in tension equals that against shearing or crushing, being equal to the smaller of the two. For VESSELS UNDER PRESSURE the pitch may be determined by the necessity for a tight joint. The above criterion generally satisfies this condition.

Ultimate strengths for rivets and plates of iron or soft steel are $S_t = 55{,}000$, $S_s = 38{,}000$, $S_c = 80{,}000$ lb. per sq. in. Working stresses for structural rivets are given in Art. 14.

General rules for design of joints:

1. Butt joints are preferred to lap joints since the latter introduce dangerous bending stresses.
2. Minimum distance from center line of rivet holes to edge of plate is $1.5d$, preferably $2d$.
3. Diameter of rivet $d = 1.2\sqrt{t}$ to $1.5\sqrt{t}$, being smaller for butt joints than for lap joints.
4. In multiple riveting the distance between rows of rivets is $1.7d$ for staggered riveting and 2 to $2.5d$ for chain riveting.
5. Thickness of straps in butt joints is $0.75t$ to $0.875t$.

Example 1. Design a double-riveted lap joint for $\frac{3}{8}$-in. plate.

There are two rivets per section and each rivet is in single shear hence $n = m = 2$. Let $d = 1.4\sqrt{t} \doteq \frac{7}{8}$ in. Then $P_S = \frac{2\pi d^2}{4} \times 38{,}000 = 45{,}500$ lb., and $P_C = 2dt \times 80{,}000 = 52{,}500$. Equating $P_t = P_S$, there results $(p - \frac{7}{8})\frac{3}{8} \times 55{,}000 = 45{,}500$ and $p = 3\frac{1}{8}$ in. Strength of un-riveted plate is $P_i = pt \times 55{,}000 = 64{,}500$, hence efficiency is $45{,}500 \div 64{,}500 = 70.5$ per cent.

Example 2. Triple-riveted butt joint (Fig. 10), has 5 rivets per section, 4 of which are in double shear, hence $n = 5$, and $m = 9$. Find the pitch for $\frac{1}{2}$-in. plate using 1-in. rivets. $P_S = \frac{9\pi d^2}{4} \times 38{,}000 = 268{,}000$. $P_C = 5dt \times 80{,}000 = 200{,}000$, hence $(p - d)t \times 55{,}000 = 200{,}000$ and $p = 8.25$ in.

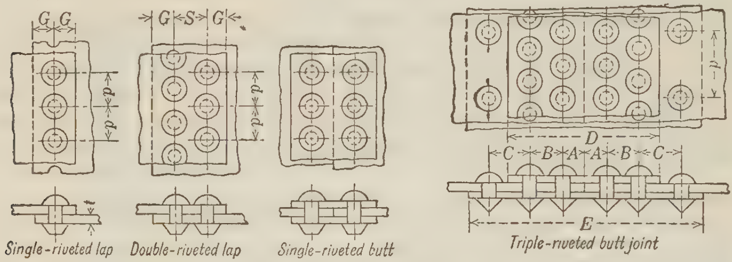

Fig. 10.—Riveted joints.

Forms of riveted joints for boilers and tanks as abstracted from recommendations of Hartford Steam Boiler Inspection and Insurance Co. are given by Fig. 10 and Tables 5 and 6.

Table 5. Dimensions of riveted lap joints

5. Cylinders and rollers

Thin cylinders. Pipes and tubes under internal pressure tend to fail in tension along an element. The bursting force is resisted by hoop tension in the shell. If the thickness of the shell is small compared with the diameter of the cylinder, stress is considered uniformly distributed over the resisting area.

Let p = internal pressure, lb. per sq. in.; d = diameter, in.; t = thickness, in.; L = length of cylinder, in.; S = unit tensile stress, lb. per sq. in. (Fig. 11). TOTAL BURSTING FORCE in any direction is pdL and RESISTING TENSION is $2StL$. Hence $S/p = d/2t$. If the shell has a riveted joint with efficiency e, then $t = pd/2Se$. This is the formula used for boilers and pipes.

Hollow spheres under internal pressure have the same stress as the transverse stress in cylindrical boilers due to pressure on the head. BURSTING FORCE = $p\pi d^2/4$; RESISTING TENSION = πdtS, hence $S/p = d/4t$. Transverse stress in a cylindrical shell is one-half the longitudinal stress.

Cylinders under external pressure. The preceding formulas do not apply since the load tends to distort the cylinder into an ellipse and distortion is accompanied by increase in stress. No rational formulas exist. For lap-welded Bessemer-steel tubes, Stewart gives the collapsing pressure P in lb. per sq. in. as follows:

$$P = 1000(1 - \sqrt{1 - 1600(t/d)^2}\,) \qquad (a)$$
$$P = 86{,}670(t/d) - 1386 \qquad (b)$$

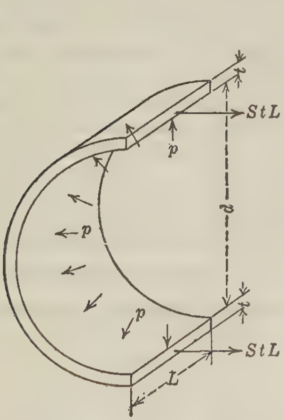

FIG. 11.

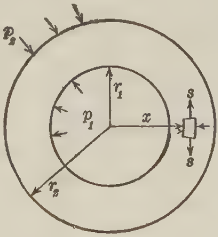

FIG. 12.

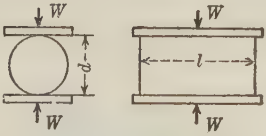

FIG. 13.

Formula (a) applies when P is less than 581 lb. per sq. in. or t/d less than 0.023, d being the outside diameter, in. For greater pressures and thicknesses use (b). Stewart also gives $P = 50{,}210{,}000\ (t/d)^3$ in place of (a).

Thick cylinders. When thickness is large compared with the diameter, tangential stress is not uniformly distributed.

Let p_1 and p_2 be internal and external pressures and r_1 and r_2 be corresponding radii (Fig. 12). Tangential stress at distance x from the center is given by LAME'S FORMULA as $S = \left[r_1^2p_1 - r_2^2p_2 + \dfrac{4r^2r_2^2}{x^2}(p_1 - p_2)\right] \Big/ 3(r_2^2 - r_1^2)$. This formula is based on a value of Poisson's ratio of ⅓. Stress decreases as x increases. If $p_2 = 0$, MAXIMUM STRESS at the inside wall is $S = \frac{1}{3}p_1(r_1^2 + 4r_2^2)/(r_2^2 - r_1^2)$. Radial compressive stress has maximum value p_1 at inside surface and minimum value p_2 at outside surface.

Rollers. Fig. 13 shows a roller of length l and diameter d placed between two plates carrying load W. Assuming the roller only to be deformed S =

$[(9W^2E)/81^2d^2)]^{1/3}$; $ld = (3W/2S)(E/2S)^{1/2}$. LOAD PER UNIT OF LENGTH $w = W/l = \frac{2}{3}dS(2S/E)^{1/2}$. Recent bridge specifications give load per linear inch $w = 600d$.

6. Beams

Notation

P = Concentrated load, lb.
W = Total distributed load, lb.
w = Unit distributed load, lb.
R = Reaction.
V = Vertical shear.
S = Normal unit stress.
S_v = Unit vertical shearing stress.
S_n = Unit horizontal shearing stress.
I = Rectangular moment of inertia.
f = Maximum deflection, in.

Bending or flexure occurs when a bar is subject to such loading that the axis assumes the form of a curve. This occurs in the case of beams, columns, and bars or blocks under eccentric load. Bending induces stresses of tension, compression, and shear.

Simple beam is a horizontal bar supported at each end without constraint, carrying vertical loads. The axis of the beam is deflected convex downward so that the upper fibers are shortened and the lower fibers lengthened. Loads and reactions at the supports are not in the same line, hence shearing stresses exist between adjacent vertical planes. CANTILEVER BEAM is a member with one end rigidly fixed and the other end projecting and free to deflect under vertical loads. CONSTRAINED BEAMS have one or both ends rigidly fixed, *e.g.*, beams with ends built into a brick wall. CONTINUOUS BEAMS have more than two supports. When a beam deflects, fibers on the convex side are in tension and those on concave side in compression. Between the two extremes is a surface of no normal stress called THE NEUTRAL SURFACE; the trace of this surface in any cross-section is called THE NEUTRAL AXIS. This axis passes through the center of gravity of the section and stress in any fiber varies directly as its distance from this axis, provided the elastic limit is not exceeded.

End reactions are found from the laws of equilibrium. Sum of loads = sum of reactions. Moment of loads about any point = moment of reactions.

Example. Figure 14 shows a simple beam with two concentrated loads. $R_1 + R_2 = 6000$. $M_a = 2000 \times 3 + 4000 \times 7 - R_2 \times 10 = 0$. $R_2 = 3400$ lb.; $R_1 = 2600$ lb.

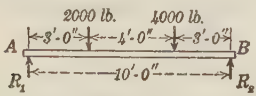

FIG. 14.

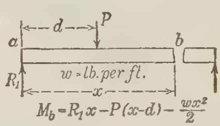

FIG. 15.

Vertical shear. At any section of a beam there is a resultant upward force on one side and an equal downward force on the other side of the section. This produces a shearing force on the section, equal in value to either force. By definition VERTICAL SHEAR on any section is the *sum of all external forces on the left of that section*, upward forces being considered positive and downward forces negative.

For a simple beam, shear at any section at a distance x from the left end is $V = R_1 - wx - P$, in which R_1 = left-end reaction, w = load per unit of length and P = sum of all concentrated loads between left end and given section. For a cantilever beam, the vertical shear at any section is the total load between that section and the free end.

Bending moment at any section of a beam is the *sum of the moments of all*

loads and reactions to the left of the section about an axis through the section. Moments with clockwise rotation are positive, counter-clockwise negative.

For a SIMPLE BEAM, the bending moment $M = R_1x - wx^2/2 - P(x - d)$ (Fig. 15). MAXIMUM MOMENT occurs at the section where vertical shear is zero, known as the DANGER SECTION. For a CANTILEVER BEAM maximum moment occurs at the point of support.

Shear and moment diagrams show graphically the value and variation of vertical shear and bending moment throughout the length of span of a beam. The ordinate under any section gives the shear or moment for that section. Table 7 gives these diagrams together with maximum shears, moments, and deflections for various types of beams and loadings.

Construction is explained in following problem, illustrated by Fig. 16: Assume a simple beam, span = 20 ft.; W = 100 lb. per linear ft.; concentrated loads of 2000 and 1000 lb. 4 ft. and 12 ft. from the left end respectively. The reactions, found by moments, are R_1 = 3000 lb., R_2 = 2000 lb. The SHEAR DIAGRAM is drawn by erecting an ordinate = 3000 at the left end noting that the distributed load causes uniform decrease in value of ordinates of 100 lb. per linear ft. while concentrated loads cause perpendicular drop equal to their value. The danger section is found graphically or, having located its position as between the concentrated loads, from the equation $R_1 - 2000 - 100x = 0$. The shear diagram for concentrated loads is composed of horizontal and vertical straight lines; for uniform load, of a uniformly sloping line. Figure 16 shows a combination. The MOMENT DIAGRAM is drawn by calculating the bending moment under each concentrated load and at the danger section. For concentrated loads this diagram is composed of straight lines intersecting at the loads; for uniform load, it is a parabola of equation $y = wlx/2 - wx^2/2$. Values of moment at points a, b, and c are $M_a = 3000 \times 4 - 50(4)^2 = 11{,}200$ lb.-ft.; $M_b = 3000 \times 10 - 2000 \times 6 - 50(10)^2 = 13{,}000$ lb.-ft. (max.); $M_c = 3000 \times 12 - 2000 \times 8 - 50(12)^2 = 12{,}800$ lb.-ft.

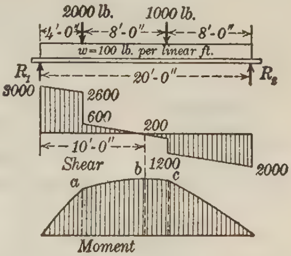

FIG. 16.—Shear and moment diagrams.

Flexure formula. From the laws of equilibrium, vertical shears and external bending moments must be resisted by equal and opposite internal shearing stresses and resisting moments. If V is the vertical shear on any section and A the section area then, assuming uniform distribution, $S = V/A$. For a simple beam maximum shear is equal to the larger reaction; for a cantilever beam it equals the total load. The internal resisting moment consists of a couple formed by the tensile and compressive stresses acting on opposite sides of the neutral axis. If S is maximum unit stress, tension or compression, and c the distance from the neutral axis to the remotest fiber, the RESISTING MOMENT in inch-pounds is given by

$$M = SI/c; \quad S = M(c/I),$$

in which S is in lb. per sq. in.; I, in.^{4}; c, in.

The term I/c is constant for any section and termed the SECTION MODULUS.

For a uniformly-loaded simple beam, $M = WL/8$, hence $W = \frac{8S}{L}\left(\frac{I}{c}\right)$ and the load varies directly as the working stress and section modulus, and inversely as the span. For a rectangular beam with breadth b and depth d, $I/c = bd^2/6$, hence the strength varies directly as the breadth and as the square of the depth. For simple and cantilever rectangular beams load $= aSbd^2/L$. For a cantilever beam with concentrated load at the end, $a = 1/6$; for distributed load, $a = 1/3$; for a simple beam with concentrated load at the center of the span, $a = 2/3$; for a distributed load, $a = 4/3$, hence the ratio of strengths is 1 : 2 : 4 : 8.

$R_1 = 0.4wL$, $R_2 = 1.1wL$, $R_3 = 1.1wL$, $R_4 = 0.4wL$

$V_{max} = 0.6wL$

$M_{max} = \frac{wL^2}{10}$

Safe loads in pounds uniformly distributed for rectangular wooden beams one inch wide, figured for allowable fiber stress of 1000 lb. per sq. in., are given in Table 8. For any rectangular beam of breadth b and allowable working stress S, multiply the tabular value by $bS/1000$.

Design of beams. For a rectangular beam of any material, type, and loading find the maximum bending moment from Table 7 or by calculation, find the ratio of the moment to $WL/8$ (value for simple beam uniformly loaded) and divide the tabular values, Table 8, by this ratio. The allowable loads as given in the table are multiplied by $bS/1000$ and divided by $M \div WL/8$.

30	133	180	235	300	370	450	535	625	725	835	950	1200

Example 1. Find the allowable concentrated load at the center of a cast-iron beam 2 in. $\times$ 6 in., span 10 ft., working stress 3000 lb. per sq. in., beam fixed at one end, supported at the other end.

From Table 7, $M = 3PL/16$ hence ratio of moments is $3/2$. Tabular value of load for beam 6 in. deep with 10-ft. span is 400 lb. Hence $P = 400 \times 2/3 \times 2 \times 3000/1000 = 1600$ lb.

Example 2. Find the width of a simple wooden beam 12 in. deep with 16-ft. span to carry 2000 lb. at the center with a working stress of 800 lb. per sq. in.

$M = PL/4$ hence the ratio of moments is 2; of stress $8/10$. Tabular value for 12-in. depth and 16-ft. span is 1000 lb. For the given conditions the load per inch width is $1000 \times 1/2 \times 8/10 = 400$ lb. Required width is $2000 \div 400 = 5$ in.

For beams of various cross-sections, express the bending moment in inch-pounds, then $M/S = I/c$ and the section is determined by the value of the section modulus. Table 9 gives properties of some common sections. For moments of inertia of other sections see Sec. 26, Table 4. For rolled shapes see Tables 21 to 24, incl.

Table 9. Properties of sections of beams

Section of beam	Moment of inertia, I	Section modulus, I/c	Radius of gyration, r
	$bd^3/12$	$bd^2/16$	$d/\sqrt{12} = 0.289d$
	$\dfrac{b_1d_1^3 - b_2d_2^3}{12}$	$\dfrac{b_1d_1^3 - b_2d_2^3}{6d_1}$	$\sqrt{\dfrac{b_1d_1^3 - b_2d_2^3}{12(b_1d_1 - b_2d_2)}}$
	$\pi d^4/64$	$\pi d^3/32$	$d/4$
	$\pi(d_1^4 - d_2^4)/64$	$\pi(d_1^4 - d_2^4)/32d_1$	$\sqrt{d_1^2 + d_2^2}/4$
	$bd^3/36$	$bd^2/24$ (min.)	$d/\sqrt{18} = 0.236d$

Deflection of beams. When a beam is subject to an external bending moment the fibers in tension are elongated and those in compression shortened. This causes the beam to deflect and the neutral surface assumes the form of a curve. The trace of this surface in the plane of bending is called the ELASTIC CURVE and the radius of curvature at any point is $R = EI/M$. Replacing R by an approximate value $R = 1 \div d^2y/dx^2$, $EId^2y/dx^2 = M$. This is integrated by expressing M as function of x and determining constants from the conditions of the problem. Maximum deflection f for various beams and loadings is given in Table 7. In general $f = PL^3/nEI$ in which n is a constant depending on the type of beam and loading. STIFFNESS $= 1/f$. Beams are often designed so that deflection shall not exceed a specified value, usually $L/360$. Since, with increase in span, deflection increases more rapidly than stress, design of long spans may be controlled by the former rather than the latter.

Example. Specifications give a working stress not to exceed 16,000 lb. per sq. in. and deflection not to exceed $L/360$. Find the distance d between adjacent I-beams for a floor to carry a uniform load of 100 lb. per sq. ft. Span = 25 ft., I-beam 10 in. deep weighing 30 lb. per ft.

$W = 100 \times 25 \times d = 2500d$; $I/c = 26.8$ (Table 21). $M = WL/8 = S(I/c)$ hence for stress of 16,000 lb. per sq. in., $2500d \times 25 \times {}^{12}/_{8} = 16{,}000 \times 26.8$, and $d = 4.6$ ft. For deflection: $L/360 = 5WL^3/384EI$. Taking $E = 30{,}000{,}000$ (Table 1). $I = 134.2$ and $W = 2500d$, $d = 3.83$ ft., hence the beams must be spaced 3.83 ft. or less center to center. Had the span been 20 ft. of less, the load to cause a stress of 16,000 would not have caused deflection greater than $L/360$.

Relation between stress and deflection. Bending moment is PL/m where m is constant, hence $PL/M = S(I/c)$ or $S = PLc/mI$. Likewise $f = PL^3/nEI$, hence $f/S = ML^2/nEc$. For any given material and section $f/S = kL^2$ in which k is constant. Hence for given load and section, if the span is doubled S is doubled but f is increased 8 times. Also, if the span is doubled and the load is reduced so that S remains constant, f is increased 4 times.

Constrained beams. The ends are built into a wall in such a manner that the tangent to the elastic curve at the end is fixed in direction. Constrained beams are stronger and stiffer than simple beams. (See Table 7.) Most beams with riveted connections have some constraint but unless the latter is known to be rigid it should be neglected and the beams treated as simple.

Continuous beams are those resting on several supports. Shears and moments are similar to those of constrained beams. Shear at any point equals the sum of all the loads and reactions to the left of the point. The moment at any section B equals the moment at any other section A plus the moment of shear at A about B, plus the moment of all intervening forces.

$$M_b = M_a + V_a x - P(x - d) - wx^2/2.$$

If two adjacent spans of a continuous beam have lengths L_1 and L_2 and unit loads w_1 and w_2, then the moments at the three points of support are connected by the theorem $M_1L_1 + 2M_2(L_1 + L_2) + M_3L_2 = - w_1L_1^3/4 - w_2L_2^3/4$. If $L_1 = L_2$ and $w_1 = w_2$ then $M_1 + 4M_2 + M_3 = - wL^2/2$. From these equations moments, shears, and reactions can be computed. Table 7 shows diagrams for uniformly loaded continuous beams of two and three equal spans. The sign of shear changes on opposite sides of the point of support and the reaction is the sum of the two values.

Impact on beams. See axial impact, Art. 3. If a load W falls through a vertical height h and strikes a horizontal beam, $S_1 = S + S(1 + 2h/d)^{1/2}$; $d_1 = d + d(1 + 2h/d)^{1/2}$, in which S_1 and d_1 are stress and deflection due to impact and S and d the corresponding values for the same load applied as a static load. S is found by the flexure formula and d from the value of f in Table 7.

Example. A cast-iron beam 1 × 6 in. has a span of 10 ft. If a weight of 50 lb. falls 2 ft. and strikes at the center of the span, find the stress due to impact.

$S = M\frac{c}{I} = \frac{50 \times 120 \times 6}{4 \times 36} = 250$ lb. per sq. in. $d = \frac{PL^3}{48EI} = \frac{50 \times (120)^3 \times 12}{48 \times 15{,}000{,}000 \times 6^3} = \frac{1}{150}$. $S_1 = 250 + 250(1 + 24 \times 150)^{1/2} = 15{,}250$ lb. per sq. in.

7. Columns

Columns are compression members whose unsupported length is more than 8 or 10 times their least dimension. Failure occurs in long columns by buckling at a stress below the elastic limit. Short columns, such as those commonly used in structures, fail by a combination of direct compressive stress and stress due to bending. The strength of such columns is a function of both section area and its least moment of inertia. SLENDERNESS RATIO is defined as l/r, in which l is the unsupported length of the column and $r = \sqrt{I/A}$ = LEAST RADIUS OF GYRATION, both generally expressed in inches.

Long columns, l/r greater than 100 or 125, fail by buckling. The load necessary to cause failure depends on the condition of the ends of the columns, those with ends rigidly fixed being stronger and stiffer than those with round ends (Fig. 17). The buckling load for round ends is given by Euler's formula as $P = \pi^2EI/l^2$, or $P/A = \pi^2E(r/l)^2$. For columns with both ends fixed, $P/A = 4\pi^2E(r/l)^2$.

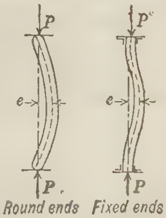

FIG. 17.—Flexure of columns.

Short columns fail by direct stress P/A and bending stress Pec/I in which Pe = bending moment due to deflection e. But $e = kl^2/c$, in which k = constant, hence total stress $S = P/A[1 + k(l/r)^2]$ and $P/A = S/[1 + k(l/r)^2]$ which is Rankine's formula, much used in design for values of l/r = 20 to 150. Values of k

recommended by *Merriman* are given in Table 10. S = allowable compressive stress in material.

Table 10. Values of constant k in Rankine's formula

Material	Both ends fixed	One end fixed, other end round	Both ends round
Timber..............	1/3,000	1.95/3,000	4/3,000
Cast iron............	1/5,000	1.95/5,000	4/5,000
Wrought iron.........	1/36,000	1.95/36,000	4/36,000
Steel................	1/25,000	1.95/25,000	4/25,000

Straight-line column formula, much used in recent specifications, is $P/A = S - c(l/r)$, in which S = working stress in material and c = a constant. The formula represents a straight line tangent to Euler's curve and gives values on the side of safety.

Allowable values of P/A for structural-steel columns

Am. Bridge Co.	A. R. E. Assn.	Gordon's Formula	New York
$19{,}000 - 100\frac{l}{r}$ 13,000 max.	$16{,}000 - 70\frac{l}{r}$ 14,000 max.	$\dfrac{12{,}500}{1 + \dfrac{l^2}{36{,}000r^2}}$	$15{,}200 - 58\frac{l}{r}$

For timber columns Am. R. R. Eng. Assn. gives $P/A = S(1 - l/60d)$ in which S = safe compressive stress along grain, l = length of column, and d = least dimension; l and d are expressed in the same unit. For $l/d < 15$, $S = P/A$. Table 11 is based on this formula with S = 1000 lb. per sq. in. For other values of S solve by proportion.

Table 11. Safe loads for wooden columns, in units of 1000 lb.
(Based on safe end-bearing compression of 1000 lb. per square inch)

Round cast-iron columns have an average ultimate strength, according to Burr, of $P/A = 30{,}500 - 165(l/d)$. This formula may be used if a factor of safety of at least 4 is introduced and l/r made less than 70. Cast iron is not good structural material.

Eccentric loads on a prism. Short blocks carrying loads not in line with their axes have a non-uniform stress distribution that is similar to the case of short columns.

Let the eccentricity of the load be e, then the moment of the load about the c.g. of the section is Pe which produces stress Pec/I. Hence the maximum unit stress is $S_1 = P/A + Pec/I = P/A(1 + ec/r^2)$. Minimum stress $S_2 = P/A(1 - ec/r^2)$. If the section is rectangular with breadth b and length unity, $S_1 = P/A(1 + 6e/b)$. The stress has straight-line distribution (Fig. 18) average value $= P/A$.

If the eccentricity for a rectangular section $= b/6$ then $S_1 = 2P/A$ and $S_2 = 0$. If e is greater than $b/6$, S_2 reverses in sign. Hence the condition to be satisfied in the design of DAMS and RETAINING WALLS, in order that there be no tension in the joint, is that the resultant pressure fall within the middle third of the section.

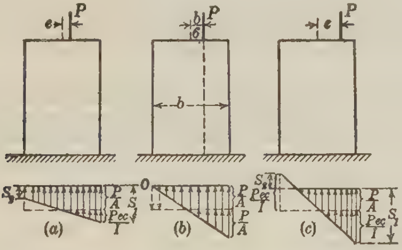

FIG. 18.

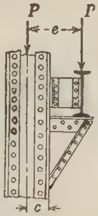

FIG. 19.

Eccentric loads on columns (Fig. 19) produce stresses which are found by combining the formulas of the preceding paragraph with Rankine's formula, hence $P/A = S/(1 + k\frac{l^2}{r^2} + \frac{ec}{r^2})$. The stresses can also be found by use of the straight-line formula. The combined stress due to axial load and bending moment should not exceed the value of P/A as given by the formula. No direct solution is possible but the problem is solved rapidly by trial.

Let P = direct load in lb. P_1 = eccentric load in lb. M = bending moment due to eccentric load in in.-lb. $= Pe$. I = moment of inertia of column in direction of bending. c = extreme fiber distance. S = allowable value of P/A as given by the column formula. A = area of section in sq. in.

The value of S should be equal to or greater than $(P + P_1)/A + Mc/I$, the combined stress due to compression and bending. In design, assume a section in excess of that required for the direct compressive load $P + P_1$ and compute the combined stress. If this is too great make another trial.

Example. Required to select a standard-channel column 20 ft. long to carry an axial load of 40,000 lb. and eccentric load of 20,000 lb., 15 in. from the center on axis 2–2. (Table 22.)

Try 12-in. @ 20.5-lb. channels back to back. $A = 12.06$, $l = 256$, $c = 6$, $r = \sqrt{I/A} = 4.61$. Hence fiber stress $= 60{,}000/12.06 + (20{,}000 \times 15 \times 6)/256 = 11{,}980$ lb. per sq. in. Allowable value of P/A, using A.R.E. formula, is $P/A = 16{,}000 - (70 \times 240)/4.61 = 12{,}360$, hence the column chosen is satisfactory.

8. Torsion of shafts

If a bar is firmly fixed at one end and a twisting couple P_p is applied at the other end (Fig. 20), the bar is twisted through an angle α and the fibers undergo shearing stress. In case of a round shaft, unit shearing stress in any section perpendicular to the axis, varies directly as the distance from the axis.

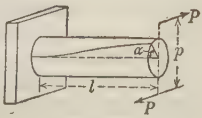

FIG. 20.

Let $M_t = P_p$ = twisting moment. S = unit shearing stress in remotest fiber. c = distance from axis to remotest fiber. J = polar moment of inertia $= I_x + I_y$. G = shearing modulus of elasticity. Then $M_t = SJ/c = aGJ/L$.

For a solid circular shaft $J = \pi d^4/32$ and $c = d/2$, therefore $M_t = \pi d^3 S/16$. If the shaft were designed to deliver H horsepower at N revolutions per minute, then $d = 68.5(H/NS)^{1/3}$. Hollow shafts are stronger than solid shafts of the same weight since the material is removed from the vicinity of the axis where the stress is small. If d_1 and d_2 represent outside and inside diameters respectively, then $J = \pi(d_1^4 - d_2^4)/32$ and $c = d_1/2$, hence $M_t = S\pi(d_1^4 - d_2^4)/16d$ and $S(d_1^4 - d_2^4)/d_1 = 321{,}000H/N$.

The angular distortion of a circular shaft in degrees is: $\alpha = 57.3M_t l/GJ = 3{,}610{,}000HL/NGJ$.

Note.—For steel the value of G varies from 12,000,000 to 15,000,000 lb. per sq. in.

9. Combined stresses

Combined flexure and torsion occurs when a twisted body undergoes bending, *e.g.*, a shaft supported by bearings at each end and carrying a pulley at its center.

Let $S = Mc/I$ = unit bending stress and $S_r = M_t c/J$ = unit shearing stress due to torsion. For circular shafts $S = 8PL/\pi d^3$; $S_r = 16M_t/\pi d^3$. S and S_v combine to produce a normal stress S_m and tangential stress S_t on an interior plane. Maximum values are:

$$S_n = \tfrac{1}{2}S \pm \sqrt{S_v^2 + (s/2)^2}; \quad S_t = \sqrt{S_v^2 + (s/2)^2}.$$

The formulas apply to any case of normal stress combined with shear. Use (+) sign to find maximum tension where S is tension and (−) sign for compression.

Combined flexure and compression occurs when a truss member is under bending as well as direct stress (Fig. 21). Maximum stress is the sum of the direct stress and the bending stresses.

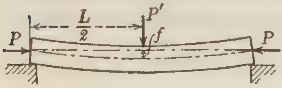

FIG. 21.

Let $S = P/A$ = direct stress and Mc/I = bending stress where M is total moment due to both P and P'. If P is small compared with P', the total stress $S = P/A + M_0c/I$, in which M_0 is the bending moment due to P' only. If compression is large, bending due to P must be considered. Moment $= Pf$, where f = maximum deflection. Total moment is $M_0 + Pf$ and resultant stress is

$$S = \frac{P}{A} + \frac{M_0c/I}{1 - PL^2/CEI},$$

in which L = the span and C is a constant having the value of 10 for hinged-end columns and 32 for fixed ends.

REINFORCED CONCRETE

Concrete is excellent material in compression and has great durability but it is weak in tension. Steel has high tensile strength but lacks durability when exposed to the atmosphere. Concrete-steel structures, in which tensile stresses are carried entirely by the steel, while concrete carries compression and at same time acts as a protective coating for steel, are ideal both as regards strength and permanency. Tension members should be all steel with concrete as a protective coating, massive compression members may be concrete only, but all members where bending is involved should be reinforced by steel bars which carry the total tensile stress. In the latter class are beams, floors, retaining walls, dams, and foundations.

Notation

Rectangular beams. (See Fig. 22.) S_s = tensile unit stress in steel. S_c = compressive unit stress in concrete. E_s = modulus of elasticity for steel. E_c = modulus of elasticity for concrete. $n = E_s/E_c$. M = moment of resistance or bending moment in general. M_s and M_c = resisting moments with respect to steel and concrete respectively. A_s = area of steel. b = breadth of beam. d = depth of beam to center of steel. k = ratio of depth of neutral axis to effective depth d. z = depth of the resultant compressive force below the top of the beam. j = ratio of the lever arm of the resisting couple to depth d. $jd = d - z$ = arm of resisting couple. p = steel ratio (not percentage). V = vertical shear. v = unit shearing stress.

T-beams (in addition to preceding). b = width of flange. b_1 = width of stem. t = thickness of stem.

Columns. A = total net area. A_s = area of longitudinal steel. A_c = area of concrete. P = total safe load.

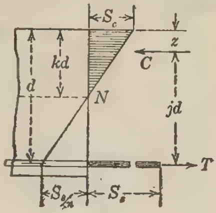

Fig. 22.

10. Reinforced-concrete beams

Steel reinforcement is placed in the tension flange to prevent failure by tension; more rarely in the compression flange to give the beam greater strength; the ends are reinforced by stirrups or by bending up the horizontal bars, or both, in order to prevent failure by diagonal tension produced by a combination of vertical and horizontal shear. Fig. 23 shows lines of maximum

Fig. 23.

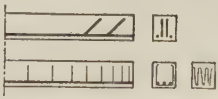

Fig. 24.

tensile stress in beams. If no reinforcement were present, the beam would tend to rupture along planes perpendicular to these lines, producing cracks as shown. Reinforcement must in general be parallel to these lines of stress. Fig. 24 shows methods of reinforcing the web against shear.

Formulas for beams

The assumptions are: perfect adhesion between steel and concrete, straight-line distribution of stress in concrete, tension in concrete neglected.

Rectangular beams. Position of neutral axis; $k = \sqrt{2pn + (pn)^2} - pn$ (**1**). Arm of resisting couple: $jd = d(1 - k/3)$; $j = 1 - k/3$ (**2**). Resisting moments: $M_s = S_s A_s jd = S_s p j b d^2$ (**3**). $M_c = S_c k j b d^2/2$ (**4**). Fiber stress for a given bending moment M is $S_s = M/A_s jd$ (**5**). $S_c = 2M/jkbd^2$ (**6**). $S_c/S_s = 2p/k$ (**7**). Steel ratio for a given stress is

$$p = \frac{1}{\dfrac{2S_s}{S_c}\left(\dfrac{S_s}{nS_c} + 1\right)} \quad (8).$$

For usual beams of 1 : 2 : 4 Portland-cement concrete, average values are, $j = 0.875$, $k = 0.375$, $p = 0.0077$, $S_s = 16{,}000$, $S_c = 650$, $n = 15$. In design, the breadth of beam b should be $0.5 \times d$ to $0.75 \times d$.

Beams that, when tested to failure, collapse by crushing concrete are said to be over-reinforced. If failure by tension occurs in the steel they are under-reinforced. If the beam is equally strong in tension and compres-

sion, that is, if stress is fully developed in both steel and concrete, the beam is said to be BALANCED. Table 12, calculated from formulas (1) to (8), shows that for balanced beams p, k, and j vary with S_s and S_c. A high value of S_c and low value of S_s demands a larger percentage of steel.

Table 12. Constants for balanced beams
(Portland-cement concrete, $n = 15$)

S_s	S_c	p	k	j	M/bd^2, in.-lb.

	700	0.0072	0.370	0.877	113.5

Example 1. Design a reinforced-concrete beam with 15-ft. span to carry a total uniform load of 400 lb. per linear ft.

Assume $S_s = 16{,}000$, $S_c = 650$. Hence $k = \frac{3}{8}$, $j = \frac{7}{8}$, $p = 0.0077$ (Table 12), $M = wl^2/8 = 400 \times 15^2 \times 12/8 = 135{,}000$ in.-lb. From Table 12, $M/bd^2 = 107.4$, hence $bd^2 = 135{,}000/107.4 = 1255$. It is now necessary to assume a ratio of b to d. Assume $b = d/2$ for the first approximation. Then $d^3 = 2510$ and $d = 13.6$ in. Making $d = 13.5$ in., $b = 7$ in., and $A_s = pbd = 0.727$ sq. in. Table 13 shows that two ⅝-in.

Table 13. Areas, weights, perimeters of bars

Size, inches	Round bars			Square bars		
	Area	Weight	Perimeter	Area	Weight	Perimeter
¼	0.049	0.167	0.785	0.062	0.213	1.000
⅜	0.110	0.376	1.178	0.141	0.478	1.500
½	0.196	0.668	1.571	0.250	0.850	2.000

(Areas in square inches, weights in pounds per linear foot; perimeter in inches)

square bars will meet this condition. Also four ½-in. round bars might be used. Economy demands a minimum number of bars, but if some bars are to be bent up for web reinforcement, more than two must be used. The quantity d is the depth to center of steel; a further depth, added for fire protection, must be figured to get the total depth. For d less than 10 in., add 1 in.; 10 to 20 in., add 1.5 in.; for d greater than 20 in., add 2 in. For slabs add from 0.75 in. to 1.25 in. The shearing strength of plain concrete is 40 lb. per sq. in. and the area resisting shear is taken as $7bd/8$. For this problem maximum shear is 3000 lb., hence the unit shearing stress $v = 3000/(0.875 \times 7 \times 13.5) = 36.4$ lb. per sq. in. and no web reinforcement is necessary.

Shearing stress and bond. Web stress is due to diagonal tension but the usual method is to consider vertical shear only. The safe unit shearing stress in 1 : 2 : 4 concrete is 40 lb. per sq. in. Stress is found from the formula $v = 8V/7bd$. Unit stress in excess of 40 lb. must be carried by stirrups or by bent up bars, or both; in the latter case the dimensions of the beam may be found from the formula $V = 120bjd$. This applies to short heavily-loaded beams for which shearing stress is the controlling factor in design. (See Example 2.) STRESSES IN STIRRUPS are found from the formula $P = mvsb = 1.14mVs/d$ (**9**), in which P = total load on stirrup, s = horizontal spacing, mV = shear to be carried by stirrups. For bars bent up at 45°, $P = 0.8mVs/d$ (**10**), in which s = horizontal projection of sloping part, and V = average shear in space s. BOND STRESS is given by the formula $u = 8V/7d\Sigma o$ (**11**), in which u = unit bond stress and Σo = the sum of the perimeters of all bars in tension reinforcement. A safe value for u is 80 lb. per sq. in. Maximum bond stress occurs at points where V is maximum; here tension steel should be run into the adjoining wall or section a sufficient distance to develop the required bond, or else bent over in the form of hook to give the required anchorage.

T-beams (Fig. 25). When the neutral axis lies in the flange use the same formulas as for rectangular beams. Removal of concrete below the neutral axis strengthens the beam by decreasing the weight. The area resisting shear is $7b_1d/8$, *i.e.*, the stem only is considered effective in shear. For independent T-beams, $b_1 \geqq b/3$, $t \gtreqless d/3$ (Fig. 25). T-beams are seldom balanced but designed from considerations of shear, headroom, and the like. When the stem joins a slab as part of a floor system, the portion of the slab with a width not exceeding one-fourth the span and not overhanging the stem more than $4t$ is considered to form the flange of a T-beam (Fig. 27).

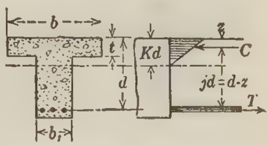

FIG. 25.

Formulas for true T-beams. The neutral axis lies in the stem and compression in the stem between axis and flange is neglected. POSITION OF NEUTRAL AXIS, $kd = (2ndA_s + bt^2)/(2nA_s + 2bt)$ (**12**). POSITION OF RESULTANT COMPRESSION, $z = \dfrac{t(3kd - 2t)}{3(2kd - t)}$ (**13**). ARM OF RESISTING COUPLE, $jd = d - z$. RESISTING MOMENT $M_s = S_sA_sjd$, $M_c = S_cbt(kd - t/2)jd/kd$ (**14**). FIBER STRESS $S_s = M/A_sjd$ (**15**); $S_c = Mkd/bt(kd - t/2)jd$ (**16**); $S_c/S_s = k/n(1 - k)$ (**17**).

Example 2. Design a continuous independent T-beam for a span of 16 ft. and load of 1000 lb. per lin. ft. (Fig. 26)

Since the beam is not homogeneous, positive and negative moments may be chosen with some latitude provided the sum is $WL/8$. The positive moment at the center of span is generally made $WL/12$, hence the negative moment at the supports is $WL/24$. In this case $+M$ = 256,000 in.-lb.; $-M$ = 128,000 in.-lb.; $V_{\max.}$ = 8000 lb. For a first approximation use $V = 120b_1jd$, which assumes bent-up bars and stirrups. This gives $b_1d = 76.2$ which is satisfied by a 6-in. × 13-in. stem. WIDTH OF FLANGE may be found by trial or by using values of Table 12 as approximations. Thus $bd^2 = 256{,}000/107.4 = 2390$, and b = 14 in. If the thickness of the flange is as much as ⅜ of d, the beam may be considered

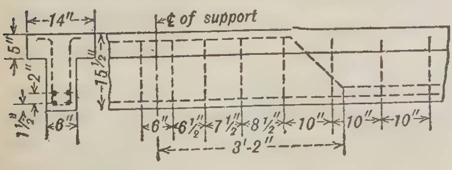

FIG. 26.—Continuous T-beam.

rectangular, hence make $t = 5$ in. The proportions of the beam are now determined except that b_1 may need to be increased to accommodate the reinforcing steel. From equation 5, or from Table 12, $A_s = 1.4$ sq. in. Conditions governing choice of bars are area and perimeter (bond unit stress is not to exceed 80 lb. per sq. in.). From Equation 11 the required perimeter is $8000 \times 8/(7 \times 13 \times 80) = 8.8$ in. These conditions are satisfied by two $\frac{5}{8}$-in. round and two $\frac{5}{8}$-in. square bars, necessitating a double row. (The practice of using both round and square bars is not generally resorted to unless a large number of similar beams or slabs is to be constructed, in which case the close figuring on steel is justified.) Maximum shear = 8000 lb. Concrete carries $6 \times 13 \times 40 = 3120$ lb., hence the shear to be carried by the stirrups = 4880 lb. Using Equation 9 and making the allowable shearing stress 10,000 lb. per sq. in., if $\frac{3}{8}$-in. square bars are used, the spacing at the end should be 6.5 in. Stirrups are extended into the point where unit shear = 40 lb. per sq. in., which in this case = $(3120/8000) \times 8 = 3.12$ ft. from center of span. The negative moment at the supports being half the maximum positive moment, two $\frac{5}{8}$-in. square bars are sufficient. The flange width (6 in.) is less than one-half the top width, but, due to the reinforcing steel, it is sufficient. Bars are generally bent up at the one-fifth points but this point should be checked by moments. Bend the bars up where they are no longer needed for tension reinforcement.

Example 3. To design a T-beam that is part of floor system; $L = 20$ ft., $M = 1{,}200{,}000$ in.-lb., $V = 20{,}000$ lb., $t = 5$ in. (Fig. 27.)

Knowing that the maximum shear is $V = 120 b_1 d \times \frac{7}{8}$, $b_1 d = 1900$. Assume $b_1 = d/2$ for the first trial, $d^2 = 380$; $d = 20$ in.; $b_1 = 10$ in. For trial solution use Table 12; $b = b_1 + 8t = 50$ in., $S_s = 16{,}000$, $S_c = 650$, $j = \frac{7}{8}$, $A_s = M/S_s jd = 4.28$ sq. in. Using this value of A_s in Equations 12 to 15, $k = 0.31$, $z = 1.94$, $j = 0.903$. Re-calculating with these values, $A_s = 4.15$, $k = 0.3$, $z = 1.91$, $j = 0.903$. The steel area may be made up of eight $\frac{3}{4}$-in. square bars giving 4.49 sq. in. Maximum bond stress (Equation 11) is 47.5 lb. per sq. in., which is satisfactory. Since $kd = 6.2$ in., the beam is a true T-beam. Applying Equations 12 to 15, $S_s = 14{,}800$, $S_c = 424$ lb. per sq. in. The steel must be placed in two rows of four bars each. The MINIMUM HORIZONTAL DISTANCE BETWEEN BARS is $3i$ where i is diameter of bar. Since the shear exceeds 40 lb. per sq. in., the bars must be bent up and stirrups used (Fig. 27). The bars are bent up in pairs and each pair is good for 15,600 lb. shear (Equation 10). Since the shear to be carried by the steel is $20{,}000 - (20 \times 10 \times 40 \times \frac{7}{8}) = 13{,}000$ lb., no stirrups are necessary in the space covered by the bent-up bars. They are put in nevertheless, at intervals of $\frac{3}{4}d$. For the remainder of the space, the interval between stirrups is to be calculated as Example 2.

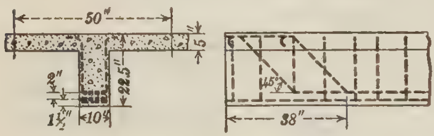

FIG. 27.—T-beam as part of floor system.

11. Reinforced-concrete columns

Reinforced-concrete columns may have longitudinal steel only, or longitudinal steel combined with circular hoops or spirals. The formula for SAFE LOAD is: $P = S_c(A_c + nA_s) = S_cA[1 + (n - 1)p]$.

Safe values are $S_c = 450$, $n = 15$, $p = 0.01$ to 0.06. The column length should not be more than 12 to 15 diameters and the concrete should be rich, 1 : 2 : 4 or better. In figuring the area of the concrete, only that within the steel should be considered; the outside shell or fire-proofing should be neglected. No advantage obtains from increasing the steel percentage above 5 or 6 since the steel can only be stressed to nS_c; with the values above, 6750 lb. per sq. in. Hoop or spiral reinforcement in addition to longitudinal steel adds considerably to the resisting strength of concrete; S_c may be taken as 650 lb. per sq. in. The area of longitudinal steel alone is to be considered in figuring the load.

Columns of rigid structural shapes encased in concrete, in which the cross-section of the steel exceeds 4 per cent., may be considered equal in strength to that of the steel column alone, figured by the usual methods, plus the strength of the concrete within the steel shapes, figured with S as 75 per cent. of normal value. The strength of the outer shell must be neglected.

Example. Design a circular reinforced column 15 ft. long to carry 100,000 lb. Assume $p = 0.02$, then $P = 450A(1 + 0.28)$; $A = 100{,}000/57 = 174$, $d = 14.9$ in. Area of steel $= 0.02 \times 174 = 3.56$. Use eight $\frac{3}{4}$-in. round rods and make the outside diameter 18 in.

BUILDING CONSTRUCTION

12. Foundations

Bearing power of soils varies widely with the nature of the soil and the load. It depends on depth of foundation, which should always extend well below frost line; on lateral confinement or inability of the soil to flow sideways, on moisture content, inclination of strata, and on distribution of pressure. For important work it is advisable to dig a test pit, apply a known load to a given area, and observe settlement. Table 14 is summarized from a number of city building codes and from typical practice not so limited.

Table 14. Safe bearing power of soils

Nature of soil	Safe load, tons per sq. ft.	
	Minimum	Maximum
Hard rock in thick beds in place	200	
Rock, well-consolidated sedimentary	15	30
Rock, soft sedimentary, or badly broken harder rock	5	10
Clay, dry, sandy	4	6
Clay, moderately dry	2	4
Clay, soft	1	2
Gravel and coarse sand, well cemented	8	10
Sand, compact and well cemented	4	6
Sand, clean dry	2	4
Quicksand, alluvial soils, etc	0.5	1

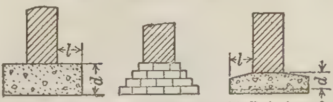
Rock will generally carry any load that can be brought upon it by masonry or concrete footings. It should be leveled off to prevent slip and all soft spots should be filled with concrete.

Clay soils vary greatly in bearing power. Slate or shale will carry any load while soft wet clay will flow or squeeze out under moderate loads. Drainage greatly improves bearing power.

Sand and gravel in thick beds, protected from the action of running water, make good foundation and may carry 6 to 10 tons per sq. ft.

Semi-liquid soils, such as quicksand and alluvium, have little bearing power and should not be relied on, if it is possible to remove them or to drive piles to a more solid sub-stratum. They can, however, support a considerable load due to hydrostatic pressure, which increases with depth.

Soil increases in compactness and bearing power with depth and is generally improved by drainage. Some settlement always occurs, and unit bearing pressures should be low. Structures should be designed for uniform settlement, hence the unit pressure on the base should be constant. This can be accomplished only by having the resultant load pass through the center of area of the base, otherwise eccentric loading occurs with consequent unequal pressures and settlement. Uniformity of pressure is facilitated by making foundation of each wall and pier separate and proportional in area to the load to be carried. This rule is not applied to dams and retaining walls, but if neglected in the case of buildings, uneven settlement may cause dangerous cracks. Compactness of clay soils may be increased by driving small piles 6 in. diameter and 6 ft. long at intervals of two to four ft. This method is not effective in sand and sandy soils since these are incompressible.



(a) Concrete (b) Brick (c) Reinforced concrete

FIG. 28.—Footings.

Footings are designed to spread a concentrated load over sufficient area so that the load per square foot falls within allowable limits. See Fig. 28. Ratio of offset l to depth d is given in Table 15. In general $l = d\sqrt{R/pf}/6$ in which R = modulus of rupture in lb. per sq. in., p = pressure in tons per sq. ft., f = factor of safety.

Timber and reinforced-concrete footings are designed as beams, the offset l being a cantilever beam under uniform load. When l is large, great masses of masonry may be avoided by the use of a grillage of wood or steel beams, or a reinforced-concrete slab with reinforcement in both directions.

Table 15. Safe offset for masonry footing courses

Kind of stone	R	p in tons per sq. ft.		
		0.5	1.0	2.0
Bluestone	5026	5.2	3.7	2.7
Granite	1844	3.2	2.2	1.6
Limestone	1377	2.8	2.0	1.4
Sandstone	1378	2.8	2.0	1.4
Good brick, natural cement mortar, after 60 days	120	0.8	0.6	0.4
Concrete, 1: 2: 4 (Portland)	400	1.6	1.1	0.7
Timber	1000	7.5	5.3	3.7

Pile foundations. Timber piles are used extensively; when below water level they last indefinitely. Piles should be 6 to 8 in. at the small end and preferably not over 14 in. at the butt. If the pile bears on hard rock it should be figured as a column, to obtain the safe load. Ordinary piles depend on friction for bearing power. The ENGINEERING NEWS FORMULAS for safe load are:

FOR PILE DRIVEN WITH DROP HAMMER, $P = 2wh/(s + 1)$.

FOR PILE DRIVEN WITH STEAM HAMMER, $P = 2wh/(s + 0.1)$ in which P = safe load, lb.; w = weight of hammer, lb.; s = penetration under last blow in inches. Piles should not be closer than 2.5 ft. center to center. The average allowable load is about 12 tons per pile; maximum, 20 tons.

Concrete piles are both cast-and-driven, and cast in place. They cost from four or five times as much as timber piles and carry 25 to 35 tons. They are commonly jet driven.

13. Masonry construction

Stone should be strong, durable and cheap; dense, hard, and uniform, and show a clean, sharp fracture free from loose grains. Stonework can be divided into two general classes, viz.: ashlar and rubble. ASHLAR MASONRY consists of stones of rectangular shape and may be further classified as coursed range and broken range (Fig. 29). Good ashlar is laid with 1 : 2 cement mortar

Coursed ashlar — Broken ashlar — Rubble (Dressed joints) — Rubble (Undressed joints)

FIG. 29.—Ashlar and rubble masonry.

Table 16. Safe working stresses for masonry construction

Kind of stone	Pounds per square inch	Tons per square foot
Granite ashlar	700	50
Limestone, hard	650	47
Marble ashlar	600	43
Soft limestone and sandstone ashlar	500	36
Rubble in Portland cement	250	18
Rubble in lime cement	140	10
Brickwork in Portland cement	350	25
Brickwork in natural cement	250	18
Brickwork in lime mortar	140	10
Concrete, Portland, 1 : 2 : 4	400	29
Concrete, Portland, 1 : 3 : 6	350	25
Concrete, natural, 1 : 2 : 5	150	10

with joints not more than ½ in. wide. The safe bearing values given in Table 16 are based on this assumption. RUBBLE MASONRY is built up of rough stones laid in mortar, the latter constitutes 20 to 50 per cent. of the total mass. Dry rubble is laid without cementing material. RUBBLE CONCRETE consists of concrete in which large stones are imbedded. RIPRAP is loose stone piled around piers and on earth to prevent wash.

The largest stones in walls should be at the bottom, individual stones laid on the broadest face; if stratified, bedding planes should be normal to stress. Porous stone should be wet before being laid. All voids should be filled with cement or mortar.

Brickwork. Strong brickwork is built of hard, well-burned brick and laid up with MORTAR composed of one part Portland cement, one part lime paste, and three parts sand. AVERAGE MORTAR consists of 1 cement, 1 lime, 6 sand. COMMON BRICK is generally $8\frac{1}{4} \times 4 \times 2\frac{1}{4}$ in. and a deep salmon color. When broken it should show fine, uniform texture and give a clear ringing sound when struck. Soft or under-burned brick is light in color and should not be used in heavy structures. Good brickwork may safely carry 20 tons per sq. ft., if laid in 1 : 3 cement mortar, and 8 tons per sq. ft. if laid in lime mortar (1 lime, 6 sand). Isolated piers of brickwork, because of increase of stress due to column action and the possibility of eccentric loading, should have unit loads of only 60 to 75 per cent. of these values. In LAYING BRICK, the structure must be tied together by alternate use of stretchers and headers. Common types of bond are shown in Fig. 30.

FIG. 30.—Bonds used in brickwork.

14. Retaining walls and dams

Retaining walls are designed to resist earth pressure. They are built of rubble masonry, rubble concrete, and reinforced concrete. Gravity walls depend upon their weight to resist sliding and the overturning effect of pressure on their backs, the only forces acting being the earth pressure and the weight of the wall.

If Fig. 31, let W = weight of wall in pounds per lin. ft., E = earth pressure in pounds per lin. ft., and R = resultant force found by combining W and E.

Failure may occur in three ways; (1) by sliding along base (AB) (2) by overturning about the toe at A; (3) by crushing the wall or the foundation at A. Sliding is prevented by friction between the wall and the ground. Gravity walls are generally safe against sliding if conditions (2) and (3) are provided for. Light reinforced-concrete walls demand special investigation and usually have a projection on the base (Fig. 34). The wall will not overturn provided the resultant falls within base AB. Only small walls are in danger of failure by overturning; in large walls, the masonry will crush at the toe before overturning. CRUSHING AT THE TOE is prevented by keeping unit loads within the safe bearing value. Pressure at the base varies uniformly from A to B (Fig. 31), due to eccentric loading.

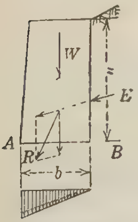


FIG. 31.

MAXIMUM UNIT LOAD (Art. 7) is given by $S = P(1 + 6e/b)/b$ in which P = vertical component of resultant pressure in lb. per lin. ft., b = width of base in ft., e = eccentricity, or distance from center of base to point where R cuts base line. The usual requirement is that the resultant pressure fall within

the middle third of the base. This insures that the maximum unit pressure will not exceed twice the average pressure (Fig. 18*b*) and no tension will exist at the heel.

Earth pressure. Lateral pressure due to the weight of earth varies directly as the depth, as in the case of water pressure. (Art. 20.) The resultant acts one-third up from the base. If the wall is surcharged, the resultant is assumed parallel with the surface (Fig. 32). The general formula is $E = kwh^2/2$ in which E = earth pressure, lb. per lin. ft.; h = height of wall, ft.; w = weight of filling per cu. ft.; k = a constant which is independent of the weight and height but depends on the angle of repose (or friction) of the material and the angle of surcharge. Rankine gives the value of k as

$$k = \cos\theta \frac{\cos\theta - \sqrt{\cos^2\theta - \cos^2\phi}}{\cos\theta + \sqrt{\cos^2\theta - \cos^2\phi}}.$$

in which θ = angle of surcharge and ϕ = angle of repose.

Table 17. Slope of repose and weights for loose earth

Kind of earth	Slope of repose	Angle of repose	Weight, lb. per cu. ft.
Sand, clean........	1.5 to 1	33° 41′	90
Sand and clay......	1.33 to 1	36° 53′	100
Clay, dry..........	1.33 to 1	36° 53′	100
Clay, damp, plastic.	2 to 1	26° 34′	100
Gravel, clean......	1.33 to 1	36° 53′	100
Soil...............	1.33 to 1	36° 53′	100
Rock, soft rotten...	1 to 1	45°	110
Cinders...........	1 to 1	45°	45

Table 18. Values of coefficient k. (*After Rankine*)

Value of θ	Angle of repose, ϕ degrees								
	0	10	15	20	25	30	35	40	45

45	....	....	....	....	....	....	....	....	0.71

Design. Small rectangular walls are often built without computation. The base is made $0.4h$ to $0.6h$, where h = height in ft. If frost is likely, the wall should extend at least four feet below the ground surface. Trapezoidal walls are more economical than rectangular. The back of the wall is often built in steps because of greater ease in constructing forms; the face generally has a batter of 1 in 12 to prevent forward settlement due to uneven pressure distribution. The base of trapezoidal walls is made $0.4h$ to $0.6h$ and the top width 1.5 to 3 ft., the larger value for walls with surcharge. Adequate drainage should be provided. The usual method in design is to lay out the wall and

then investigate for stability. Many methods are used, the following example illustrates a common method.

Example. To design a concrete retaining wall with 16 ft. clear height to withstand the pressure of soil weighing 100 lb. per cu. ft. and having an angle of repose of 37°; surcharge angle = 15°.

The wall weighs 150 lb. per cu. ft. Assuming frost likely, the total height will be 20 ft. Width of base is determined by the allowable bearing pressure at the toe, the softer the foundation, the wider the base. Assume $b = 0.45h = 9$ ft. Take top width as 2 ft. Batter of face is 1 : 12. With these data lay out wall as in Fig. 32. Draw vertical line BC. Assume earth pressure to act on this line one-third up from B, as though line BC were the back of the wall. The weight of the triangle of earth BCD is combined with the earth pressure. The resultant of these two forces combined with the weight of the wall gives the final resultant. From Table 18, interpolating for $\phi = 37$ and $\theta = 15$, the value of k is 0.276, hence earth pressure $E = kwh^2/2 = 0.276 \times 100 \times 20^2/2 = 5520$ lb. per linear ft. of wall. The weight of triangle BCD and the position of its center of gravity are found by scaling from Fig. 32; area = 54.3 sq. ft., hence weight = 5430 lb. per linear ft. The resultant of this force and the earth pressure = 8740 lb. The weight of the wall at 150 lb. per cu. ft. = 16,500 lb. per linear ft. See Sec. 26, Art. 13, for center of gravity of wall. Final resultant is 23,800 lb., cutting the base 1.2 ft. from the center; vertical component $P = 22{,}800$. Maximum unit pressure $= P(1 + 6e/b)/b = 22{,}800 \times 1.8/9 = 4560$ lb. per sq. ft. Table 14 shows this to be a conservative value for moderately dry soil. The fact that the resultant falls within the middle third of the base assures absence of tension at the heel. The horizontal component of the resultant is 5500 lb. The coefficient of friction for concrete on dry clay and sand varies from 0.4 to 0.5, hence the factor of safety against sliding is 1.6 to 2.1 which is satisfactory.

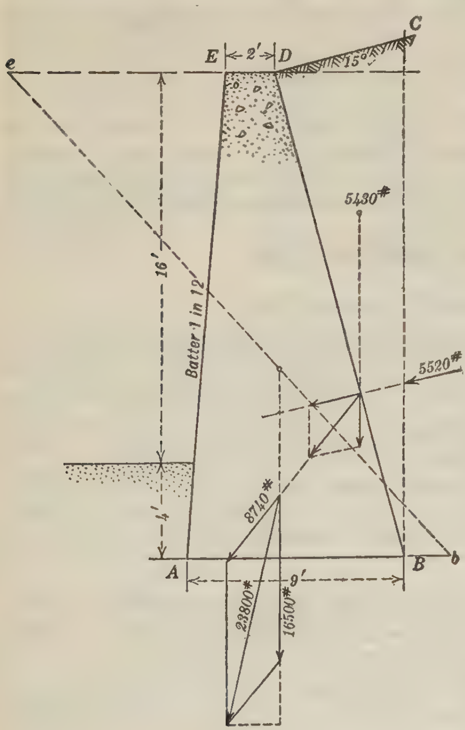

FIG. 32.

FIG. 33.

FIG. 34.

Some designers consider earth pressure to act horizontally instead of parallel to the surface; this increases the overturning moment and hence is on the side of safety. Offsets for foundations are often specified. Fig. 33 shows a conventional type of wall with offset foundation, stepped back, and drainage system.

Masonry dams are designed to meet the same conditions as retaining walls, and in addition the requirement that the foundation must be impermeable. Water pressure in lb. per ft. of run is $P = wh^2/2 = 31.25h^2$, where h is the total head in feet. P acts one-third up from the base. The foundation should be

on rock and impervious; if water seeps under the dam or into any horizontal joint, it will exert hydrostatic pressure upward and reduce the effective weight of the masonry, hence cut-off walls are built at the heel and the foundation is drained. Some specifications provide for hydrostatic pressure by assuming full static head at the heel, diminishing uniformly to zero at the toe, the resultant upward pressure is then one-half the total static pressure and acts one-third the distance from heel to toe. For masonry dams under 30 ft. in height a trapezoidal section is economical. Top width should be 4 to 5 ft., height such as to be three or more feet above high water, back with slight batter, and base such that the resultant force falls within the middle third. (See Retaining walls.) Safe bearing pressure for rubble or concrete dam on rock foundation is 10 to 12 tons per sq. ft. Typical small dam sections are shown in Fig. 35.

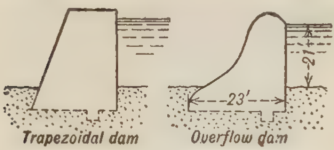

FIG. 35.—Typical dam sections.

STEEL CONSTRUCTION

15. Strength of iron and steel

Cast iron, wrought iron, and steel are alloys of iron and carbon which also contain manganese, silicon, sulphur, and phosphorus. The percentage of carbon has the determining influence on the relative properties of the materials.

Cast iron contains 2 to 4 per cent. CARBON and varying amounts of other elements. Its TENSILE STRENGTH varies from 18,000 to 20,000 lb. per sq. in. and COMPRESSIVE STRENGTH averages 90,000. It has poorly defined ELASTIC LIMIT and no YIELD POINT. MODULUS OF ELASTICITY is 12,000,000 to 18,000,000 lb. per sq. in. Resilience and work to rupture are low hence it has small RESISTANCE TO SHOCK.

As a STRUCTURAL MATERIAL cast iron is unreliable, due to the possibility of hidden defects such as blow holes, cracks, and to internal stresses due to cooling; its use is often prohibited. It is used for a great variety of machine parts, pipe under low pressure, fittings, and short columns under steady load.

Malleable cast iron is made by slow annealing of hard white-iron castings packed in iron oxide. This process de-carbonizes the iron and produces a malleable material with TENSILE STRENGTH of 40,000 lb. per sq. in. and ELONGATION 8 to 10 times that of cast iron.

Malleable iron is used for pipe fittings and small machine parts, but because de-carbonization extends but a short distance below the surface its use is limited to small castings.

Wrought iron is made without fusion; has carbon content 0.05-0.3 per cent.; is tough, ductile, malleable, easily welded but not readily fusible. It shows a fibrous structure on fracture. Its ULTIMATE STRENGTH in tension is 40,000 to 50,000 lb. per sq. in., shear 40,000; MODULUS OF ELASTICITY, 28,000,000.

It is tougher and resists CORROSION better than soft steel but the latter has entirely superseded it for STRUCTURAL WORK due to its lower cost and greater strength.

Steel is an iron-carbon alloy intermediate in composition between cast iron and wrought iron but has higher specific gravity and strength than either. It is made chiefly by three processes, the crucible, open-hearth, and Bessemer;

the quality and relative cost decrease in the order named. Strength is a function chiefly of the carbon content, a rough rule is: $S_t = 45{,}000 + 108{,}000\, C$, in which S_t is tensile strength of un-annealed acid open-hearth steel and C is the carbon content in per cent. A general classification according to carbon content is as follows:

Soft, 0.05–0.20 per cent. C, not temperable, easily welded; medium, 0.15–0.40 per cent. C, poor temper, weldable; hard, 0.30–0.70 per cent. C, good temper, not easily welded; very hard, 0.60–1.00 per cent. C., high temper, not weldable.

Table 19. Average properties of steel

Kind of steel	Elastic limit	Tensile strength	Elongation, per cent	Remarks
Structural-steel rivets. .	30,000	55,000	30	Modulus of elasticity for all grades, 30,000,000; shearing modulus, 10 to 15 million
Structural, rolled shapes	35,000	60,000	27	
Machinery steel.	40,000	75,000	20	
Axle steel.	60,000	100,000	15	
Spring steel.	60,000	125,000	12	
Cable-wire steel.	100,000	200,000	8	

Strength increases and elongation decreases with carbon content. Roughly the percentage of elongation $= 1{,}500{,}000/S_t$.

Nickel steel contains about 3.5 per cent. nickel; it is used to a small extent for structural purposes. Heat-treated nickel steel may have tensile strength in excess of 200,000. Structural nickel steel has an elastic limit 15 per cent. higher and ultimate strength 25 per cent. higher than ordinary structural steel.

16. Steel structures

Steel structures are fabricated of standard rolled-steel shapes. Properties of selected I-beams, channels, and angles, are given in Tables 21 to 24. Safe rules for design follow:

Loads. For structures carrying moving loads add 25 per cent. to the stresses caused by said loads; for wind pressure, allow 20 lb. per sq. ft. on the vertical projection of all surfaces exposed to wind; allow 25 lb. per sq. ft. for snow for slopes under 20°; for other slopes use one pound less for each degree of slope above 20°.

Safe unit stresses for the sum of dead, live, impact, and wind stresses are as follows:

	Lb. per sq. in.
Tension, net section.	16,000
Direct compression.	16,000
Bending on extreme fibers of rolled shapes.	16,000
Shear on pins and shop rivets.	12,000
Shear on bolts and field rivets.	10,000
Shear on rolled sections.	10,000
Bearing pressure on shop rivets and pins.	24,000
Bearing pressure on field rivets and bolts.	20,000

Axial compression allowable on gross section of columns for ratio of l/r up to 120 = $19{,}000 - 100(l/r)$ lb. per sq. in., where l = effective length of member and r is radius of gyration of section, both in inches. For values of l/r in excess of 120 use the following quantities:

Ratio (l/r).	130	140	150	160	170	180	190
Quantity.	6500	6000	5500	5000	4500	4000	3500

Compression members in the main structure should have a length not in excess of 120 × *least radius of gyration;* for secondary members this ratio should not exceed 200.

Beams and girders should not have an unsupported length in excess of 40 × *width of compression flange.*

Riveting. Mininum distance between rivet holes should be 3 diameters. For built-up shapes the maximum pitch (spacing) in line of stress is 6 in. for ⅞-in. rivets, 5 in. for ¾-in., 4½ in. for ⅝-in., and 4 in. for ½-in. rivets.

Standard beam connections are given in Fig. 36 and STANDARD GAUGES FOR ANGLES in Table 20. PLATES for connecting structural members and size

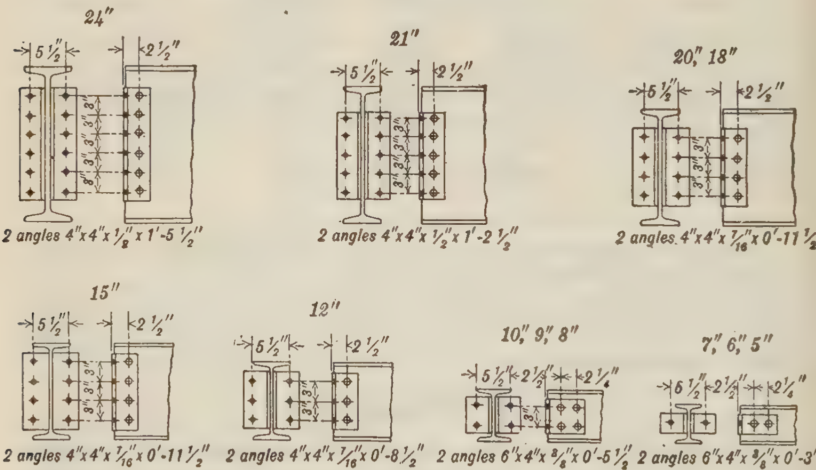

FIG. 36.—Standard beam connections.

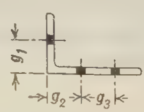
Table 20. Gages for angles, inches

Leg	8	7	6	5	4	3½	3	2½	2	1¾	1½	1⅜	1¼	1	¾
g_1	4½	4	3½	3	2½	2	1¾	1⅜	1⅛	1	⅞	⅞	¾	⅝	½
g_2	3	2½	2½	2	...	...	...	...	...	...	...	...	...	...	...
g_3	3	3	2¼	1¾	...	...	...	...	...	...	...	...	...	...	...
Maximum rivet.....	1⅛	1	⅞	⅞	⅞	⅞	⅞	¾	⅝	½	⅜	⅜	⅜	½	½



and number of rivets should be designed for shearing strength of rivets and bearing strength of plates and webs of members to be connected. See Art. 4.

Properties of selected I-beams are given in Table 21.

I is moment of inertia, r is radius of gyration, S is section modulus = (I/c); coefficient of strength is the product of the span in ft. and the safe uniformly-distributed load in lb. For concentrated load at center of span divide coefficient by two. Axis 1–1 is perpendicular to the web at the center, axis 2–2 is coincident with the web.

Example. Select an I-beam with a span of 20 ft. to carry a uniformly-distributed load of 10,000 lb.

(a) By calculation, the moment, $M = WL/8 = 10{,}000 \times 20 \times 12/8 = 300{,}000$. Section modulus (S) = moment/stress = 300,000/16,000 = 18.75. From Table 21 a 9-in. beam weighing 21 lb. per ft. is the lightest section that fulfills the requirements.

Table 21. Properties of selected standard I-beams (*Carnegie*)

	4.0	1.19	1.410	0.170	1.6	1.17	1.1	0.42	0.44	1.29	12,000

(b) By use of coefficient of strength, multiply the load by the span in ft., 10,000 × 20 = 200,000, then select a 9-in. @ 21-lb. I-beam, coefficient of strength = 201,000.

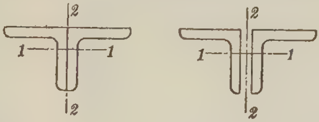
Properties of channels are given in Table 22. The symbols are the same as Table 21 except that x is the distance from the neutral axis to the back face of the web. Two channels back to back and connected with lattice bars is a common type of column. The distance back-to-back of channels should equal or exceed the tabular to develop the full strength of the column.

Example. Find the safe load for a column built of two 12-in. @ 25-lb. channels spaced 7½ in. back-to-back and properly latticed, if the unsupported length is 36 ft.

Since the distance back-to-back exceeds the value in Table 22, the least radius of gyration is about the axis 1–1 and is 4.43. Load $P = A(19{,}000 - 100(l/r)) = 14.70 \times \left(19{,}000 - \frac{100 \times 36 \times 12}{4.43}\right) = 136{,}000$ lb.

Properties of angles. Tables 23 and 24 give the properties of selected standard angles and radii of gyration for two angles separated by varying thicknesses of connecting plates. This latter arrangement is the usual form of member for roof trusses and light bridges; angles with unequal legs give more economical arrangement because the radii of gyration about axes 1–1 and 2–2 are more nearly equal.

Table 23. Properties of equal-leg angles



Single angle: Size, inches	Single angle: Weight, pounds per foot	Two angles, area, square inches	Radii of gyration, inches: Axis 1–1	Axis 2–2: In contact	Axis 2–2: ¼ in. apart	Axis 2–2: ⅜ in. apart	Axis 2–2: ½ in. apart
8 × 8 × 1⅛	56.9	33.46	2.42	3.42	3.51	3.55	3.60

¼	6.6	3.88	1.25	1.66	1.75	1.79	1.84
3½ × 3½ × 13/16	17.1	10.06	1.02	1.55	1.65	1.70	1.75
¼	5.8	3.38	1.09	1.46	1.55	1.59	1.64
3 × 3 × ⅝	11.5	6.72	0.88	1.32	1.41	1.46	1.51
¼	4.9	2.88	0.93	1.25	1.34	1.38	1.43
2½ × 2½ × ½	7.7	4.50	0.74	1.09	1.19	1.24	1.29
¼	4.1	2.38	0.77	1.05	1.14	1.19	1.24
2 × 2 × 7/16	5.3	3.12	0.59	0.88	0.98	1.03	1.08
¼	3.19	1.88	0.61	0.85	0.94	0.99	1.04

Example. Design the compression chord of a roof truss for a maximum load of 35,000 lb. and unsupported length of 10 ft.

Assume as the first approximation that $l/r = 100$, hence $P/A = 9000$ and an area of 3.9 sq. in. is required. Try two angles 4 × 3 × 5/16 in. with ⅜-in. connecting plates. The least radius of gyration is 1.27 and area is 4.18. $P = 4.18 \times (19{,}000 - 100 \times {}^{120}/_{27}) =$ 39,800 lb., which is satisfactory. Two 4 × 4 × ¼-in. angles also meet the requirements and are somewhat lighter. If this member is subjected to bending stresses by the purlins, it should be designed by the formula of Art. 7 for combined compression and bending.

HYDRAULICS

17. Physical properties of water

Weight of water is usually taken as 62.5 lb. per cu. ft., or 8.355 lb. per U. S. gal. Accurate weights for pure water are given in Table 1. Sea water weighs 64 lb. per cu. ft., Great Salt Lake water, 69 to 76; sewage, 62.4 to 62.7; ice, 57.2 to 57.5 lb. per cu. ft.

Compressibility varies with temperature and pressure. The average value of the BULK MODULUS OF ELASTICITY for low temperature and pressures less than 1000 lb. per sq. in. is 294,000 lb. per sq. in. This value increases with both temperature and pressure. A pressure of 1000 lb. per sq. in. decreases the volume only 0.33 per cent., hence water may be considered incompressible.

18. Atmospheric pressure

MEAN ATMOSPHERIC PRESSURE at sea level is 14.7 lb. per sq. in.; it causes mercury to rise in an exhausted tube to a height of 30 in.; the corresponding height of a water column is 34 ft. Water boils at this pressure at 212° F.; as altitude increases, atmospheric pressure and the boiling point of water decrease. If the air at the top of a barometer tube is only partially exhausted, the height of the mercury column measures the difference in pressure inside and outside. PRESSURES BELOW ATMOSPHERE are often measured in inches of mercury, each inch corresponding to negative or suction pressure of 0.491 lb. per sq. in. Atmospheric pressure has marked effect on the flow of water but where it acts on all parts of a system its effect is neutralized. Pressures below atmosphere are treated as negative pressures and corresponding heads as negative heads.

Table 25. Weight of distilled water

Temperature, degrees F.	Pounds per cubic foot	Temperature, degrees F.	Pounds per cubic foot
32	62.42	130	61.55
39.3 (max.)	62.424	140	61.39
50	62.41	150	61.20
60	62.37	160	61.01
70	62.30	170	60.80
80	62.22	180	60.59
90	62.12	190	60.36
100	62.00	200	60.14
110	61.86	210	59.89
120	61.72	212	59.84

19. Transmission of pressure

Pascal's law. A perfect liquid is unable to withstand tangential stress, hence pressure at any point in a liquid acts with equal intensity in every direction. If water in a closed vessel be subjected to unit pressure p, this pressure is transmitted with undiminished intensity throughout the liquid; the total pressure on any area A will be pA and its direction will be normal to that area. This principle is applied in the hydraulic press, jack, accumulator, and in heavy hydraulic machinery such as punching and riveting machines.

Hydraulic press consists of two cylinders of different diameters, fitted with pistons, and connected by a pipe. If a force P is applied to the small piston it produces pressure on the water which is transmitted to the large piston and enables it to support a load W such that $P/W = d^2/D^2$. This equation is modified by friction of the packing and, if the pistons are not at same elevation, by pressure caused by the difference in head. D/d may be made any desired value, hence it is possible to obtain forces limited only by the ability of the machines to withstand the strain.

20. Pressure due to weight

Unit pressure on a horizontal layer at distance h below the surface in a body of still water is $p = wh$ where w = weight of a cubic unit of water and h = depth below the surface, called HEAD. Pressure per sq. ft. is $p = 62.5h$ and per sq. in. is $p = 0.434h$; pressures are frequently expressed also in feet of head. INTENSITY OF PRESSURE depends only on the density of the liquid and the head; it is independent of the size and shape of the containing vessel and the amount of liquid present.

21. Total pressure and center of pressure

Total normal pressure on any submerged area is $p_n = wAh_0$. In common units, $w = 62.5$, A = total area in sq. ft., and h_0 = the vertical distance from the surface to the center of gravity of the area in ft.

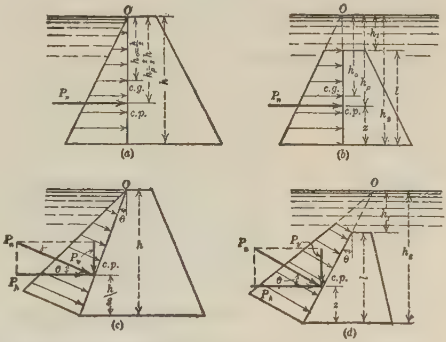
In the case of a VERTICAL DAM of height = h, the area per lin. ft. is h and $h_0 = h/2$. hence $P_n = wh^2/2$.

Pressure in a given direction is $P_1 = P_n \cos\theta = wA_1h_0$, where θ is the angle between the given direction and the normal and A_1 is the projection of the submerged surface on a plane normal to the given direction.

Examples. Horizontal pressure on a DAM is $P_n = wh^2/2$ whether the up-stream face is vertical or inclined. The driving pressure of a PUMP PLUNGER is the same whether the latter is plane or spherical.

Center of pressure of a submerged surface is the point of application of the resultant pressure.

For a RECTANGLE with the top in the liquid surface, the depth of the center of pressure is ⅔h. For submerged rectangles the total pressures and centers of pressure may be found by constructing pressure diagrams (Fig. 42). The area of the diagram represents total pressure and the c.g. of the diagram is opposite the center of pressure. A general rule for location of the center of pressure is: $y_p = I/S$, where I is moment of inertia of the area (see Sec. 26, Art. 14), S is the moment of the area (= area × distance of c.g. from the axis), and y_p is the arm of the center of pressure, all with respect to an axis which is the intersection of the plane of the submerged surface with the water level. A more convenient form is $y_p = y_0 + k_0^2/y_0$, where y_0 is the distance from the axis to the c.g. and k_0 is the radius of gyration of the submerged area about its c.g. The distance k_0^2/y_0 becomes negligible when the head exceeds three or four times the vertical dimensions of the submerged surface.



a. $P_n = P_h = wh^2/2$

b. $P_n = w(h_2^2 - h_1^2)/2 = wl(l + 2h_1)/2$

$$h_p = \frac{2}{3}\left(\frac{h_2^3 - h_1^3}{h_2^2 - h_1^2}\right). \quad z = \frac{l}{3}\left(\frac{l + 3h_1}{l + 2h_1}\right)$$

c. $P_n = wh^2/2 \cos\theta$. $P_h = wh^2/2$. $P_v = (wh^2 \tan\theta)/2$

d. $P_n = wl(l + 2h_1)/2 \cos\theta$

$P_h = wl(l + 2h_1)/2 = P_h \tan\theta$

$z = l(l + 3h_1)/3(l + 2h_1)$

FIG. 42.

Example 1. A square gate, 2 × 2 ft., inclined 60° from the horizontal, with its c.g. 5 ft. below the surface, covers a rectangular opening (Fig. 43). The gate is hinged at the upper edge and it is required to find the moment about the hinge necessary to open the gate.

$P_n = wAh_0 = 62.5 \times 4 \times 5 = 1250$ lb. $y_0 = 5 \sec 60° = 5.77$ ft. $y_p = 5.77 + 0.333/5.77 = 5.828$ ft. Moment about hinge = 1250 × 1.05 = 1320 lb.-ft.

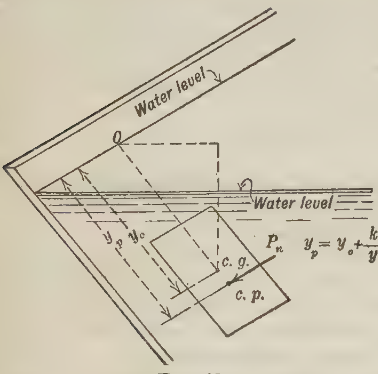


FIG. 43.

Example 2. A vertical wall has 15 ft. of water on one side and 6 ft. on the other. Find the overturning moment on the wall per lin. ft.

$P_1 = 62.5 \times 15^2/2 = 7040$ lb. $P_2 = 62.5 \times 6^2/2 = 1125$ lb. $M = 7040 \times 15/3 - 1125 \times 6/3 = 32{,}950$ lb.-ft.

22. Loss of weight in water. Flotation

Archimedes' principle. A submerged body loses an amount of weight equal to that of a volume of water which is the same as the volume of the submerged body. A body weighing W lb. in air will weigh submerged $W(1 - 62.5/d)$ where d is density of the body in lb. per cu. ft.

Example. If water percolates under a rectangular masonry dam in such a way that full hydrostatic pressure is developed, the upward pressure of water decreases the stability against overturning as though the unit weight of the masonry were decreased 62.5 lb. per cu. ft. Such percolation should be prevented by cut-off walls and drains.

Depth of flotation. A floating body displaces a volume of water that has weight equal to that of the body. To find the depth of flotation y, equate the weight of the body to $62.5 \times$ volume of water expressed in terms of y.

Example. A loaded ship having vertical sides has a waterline enclosing 10,000 sq. ft. What is the change of draft (fresh water) when 500 tons of coal have been burned? Solution, $500 \times 2000 = y \times 10{,}000 \times 62.5$. $y = 1.6$ ft

Stability of flotation. The resultant upward pressure on a floating body acts through the c.g. of the displaced water. This point is called the CENTER OF BUOYANCY. If this resultant also acts through the c.g. of the body the latter is in equilibrium. Otherwise the body will roll under the action of an unbalanced couple.

FIG. 44.

Consider a symmetrical floating body to be displaced from its position of equilibrium through angle θ (Fig. 44). The resultant water pressure through the center of bouyancy B will intersect the axis of symmetry at M, THE METACENTER. The equilibrium of the body is stable, neutral, or unstable according as M is above, coincident with, or below the c.g. of the body.

23. Pressure on gates and tanks

Resultant pressure on a submerged gate is due to the difference of head h on the two sides and is of uniform intensity over the whole of the submerged surface. Pressure $P = wAh$; the intensity is constant and the center of pressure and c.g. coincide.

Unit tensile stress in a pipe or circular tank is given by the formula for HOOP TENSION, $Pd = 2St$, where P is internal pressure in lb. per sq. in., d is diameter in inches, t is thickness of shell, and S is the unit stress in lb. per sq. in. The lower limit of applicability is $d = 30t$, the expression applies to pipes, steel tanks, steel bands for wood stave pipe and steel for reinforced concrete tanks. For thick cylinders see Art. 5.

Example. A standpipe 60 ft. high and 30 ft. diameter is to be built of riveted steel plates, the efficiency of the joints being 70 per cent. and allowable stress 10,000 lb. per sq. in.

Divide the pipe into any number of sections (say five) and design each section for the internal pressure at its lower edge. For the lowest section, $P = 0.434 \times 60 = 26.04$; therefore $26.04 \times 360 = 2 \times 10{,}000 \times t \times 0.70$, and $t = 0.67$ in. or ¾-in. plates. The other sections would be made of ½-, ⅜-, and ¼-in. plates respectively. The same principle of division applies to spacing steel bands on wood-stave tanks and reinforcing bars in concrete tanks.

24. General laws of flow

Torricelli's theorem. The velocity of flow of a jet discharging under a head of h ft. is the same as the velocity acquired by a body falling freely through the height h. Thus $v = \sqrt{2gh}$ = velocity in ft. per sec.

Bernouilli's theorem. For steady frictionless flow the sum of the pressure head and the velocity head equals the hydrostatic head that obtains when there is no flow. For actual conditions involving friction, the sum of the pressure head, velocity head, and elevation head above some assumed datum plane at some station 1 equals the sum of the corresponding heads at any other station 2, plus or minus FRICTION HEAD h_f; plus if 2 is downstream and minus if upstream.

If $h = p/w$ = pressure head, and z = elevation head above the assumed datum plane, $h_1 + z_1 + v_1^2/2g = h_2 + z_2 + v_2^2/2g + h_f$. Multiplying both sides of this equation by the weight of fluid passing per unit of time, the expression states that the total energy per unit

of time available at 1 equals the total energy at 2 plus the energy lost between 1 and 2. Bernouilli's theorem is a form of statement of the law of the conservation of energy and is the basis of most hydraulic formulas.

25. Flow from orifices and mouthpieces

Coefficients. The discharge from a standard orifice (Fig. 45) contracts, at a distance $d/2$ from the plane of the orifice, to an area that is 62 per cent. of that orifice. Pressure head does not become zero and velocity does not attain its value $v = \sqrt{2gh}$ until this contracted section is reached. Head should be measured to the center of pressure but if h is 3 or 4 times d the error involved by reading h to the center of the orifice is small. The ratio of the contracted area to the area of the orifice is C' = the COEFFICIENT OF CONTRACTION. Actual velocity is slightly less than theoretical and is given by $v = C_1\sqrt{2gh}$ where C_1 is COEFFICIENT OF VELOCITY. Discharge in cu. ft. per sec. is the product of velocity and area of the contracted jet and is

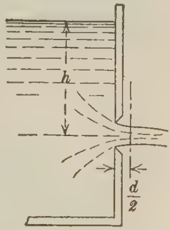

FIG. 45.—Standard orifice.

$$q = C'C_1A\sqrt{2gh} = CA\sqrt{2gh},$$

where C is the COEFFICIENT OF DISCHARGE and A is the area of the orifice in sq. ft.

Standard orifice gives an accurate means of measuring the flow of water. The center of the orifice should be at least $3d$ from the sides and bottom of the tank; the edges should be sharp in order that full contraction may be developed. For SMALL ORIFICES, 1 in. or less in diameter, C may be taken as 0.61 for circular and 0.62 for square orifices. For LARGER ORIFICES and HIGH HEADS the average value of C = 0.597 for circular orifices and 0.604 for square orifices may be used. A precision involving an error of less than 3 per cent. may be expected. If greater accuracy is desired, the orifice should be calibrated or reference had to a table of coefficients in any standard work on Hydraulics. An error less than 1 per cent. may be obtained by calibration.

Large orifices under low heads. Variation of pressure in the place of the orifice is so great that the preceding discharge formula does not hold. To calculate discharge it is necessary to divide the orifice into elementary horizontal strips $x\,dy$ under head y and integrate the discharges through these strips.

For a rectangular orifice of breadth b: $q = \frac{2}{3}C\sqrt{2g}\cdot b(h_2^{3/2} - h_1^{3/2})$ where h_1 and h_2 are the heads on the top and bottom of the orifice respectively. This expression should be used if the head on the center of gravity of the orifice ($h_{c.g.}$) is less than three times the depth of the orifice.

Submerged orifices. Flow is due to the difference in level on the two sides of the orifice and does not depend on the depth of submergence; it is slightly less than for discharge into the atmosphere, the average difference being about 1 per cent. For large orifices the difference is negligible; for orifices 1 in. in diameter or less it may be 2 per cent. The value of C = 0.60 is in general use.

Velocity of approach. If water in a channel approaching an orifice has velocity v_a, the head on the orifice is increased by the velocity head $h_v = v^2_a/2g$ and the EFFECTIVE HEAD is $H = h + v^2_a/2g$. Then $q = CA\sqrt{2gH}$. If the approaching channel and the orifice have areas a and A respectively,

$$v = C_1\sqrt{\frac{2gh}{1 - C^2\left(\frac{A}{a}\right)^2}};\quad q = A\sqrt{\frac{2gh}{\left(\frac{1}{C}\right)^2 - \left(\frac{A}{a}\right)^2}}.$$

For a RECTANGULAR ORIFICE under low heads,

$$q = \tfrac{2}{3}C\sqrt{2g} \cdot b[(h_2 + h_v)^{3/2} - (h_1 + h_v)^{3/2}].$$

Suppression of contraction is effected by an internal projection at the perimeter of the orifice. Suppression increases discharge. For a square orifice with one side suppressed the increase is about 3.5 per cent.; two sides, 7.5 per cent. For rectangles with the lower edge suppressed the increase is 6 to 7 per cent., if $b = 4d$, and 8 to 12 per cent., if $b = 20d$. Avoid suppressed orifices for accurate work.

Discharge under a falling head. If Y is area enclosed by the waterline when the head on an orifice is y, the time for the head to fall from H to h is

$$t = \int_h^H \frac{Yy^{-\frac{1}{2}}}{CA\sqrt{2g}}dy,$$

where Y is, in general, some function of y. If the cross-section is constant and equal to a, the time to empty a vessel is $t = 2a\sqrt{H}/CA\sqrt{2g}$, which is twice that required to discharge a similar amount under a constant head H.

The miner's inch is a unit of flow used in mining and irrigating work; it is rapidly becoming obsolete. It is defined as the discharge from an orifice one inch square under a head on its center of 6.5 in. The value of this unit and its definition vary in different states. The legal equivalent in California is 40 miner's inches = 1 cu. ft. per sec., in Colorado 38.4, while in Arizona, Idaho, Nevada and Utah, the value is 50, by common agreement.

Flow under pressure. When water in a closed vessel is under unit pressure p in addition to its own weight, the velocity and discharge from an orifice are found by computing the equivalent head in feet, $H = h + p/w$. If discharge takes place into a vessel in which the unit pressure is p_0, the equivalent head is $H = h + p/w - p_0/w$.

Example. A 1-in. circular orifice under a head of 10 ft. and an additional pressure of 10 lb. per sq. in. discharges into a 26-in. vacuum and it is desired to find the discharge.

The 26-in. vacuum is equivalent to a negative head of $26 \times 34/30 = 29.5$ ft. which increases the effective head, hence $H = 10 + 10 \times 2.304 + 29.5 = 62.5$ ft. $q = CA\sqrt{2gH}$ $= 0.61 \times 0.00546\sqrt{64.4 \times 62.5} = 0.212$ cu. ft. per sec.

26. Tubes, nozzles, and jets

Short tubes whose lengths are 2 to 3 diameters may be treated in the same manner as orifices. LONG TUBES are classified as pipes. The addition of a short tube to an orifice decreases velocity but INCREASES discharge, although friction losses are also increased. This is due to the fact that the jet after passing the contracted section re-expands to fill the whole cross-section of the tube. Velocity at the contracted section is greater than that at the discharge end of the tube, pressure is correspondingly less (Bernouilli's theorem), and hence below atmospheric, if discharge is into the atmosphere. This negative pressure increases the effective head and discharge is increased. Fig. 46 shows common types of tubes and end connections.

FIG. 46.—Short tubes and mouthpieces.

(a) is the STANDARD SHORT TUBE for which $C' = 1.0$, $C_1 = C = 0.82$, provided that the jet re-expands to fill the tube. For high heads the discharge will jump clear of tube and the device becomes a standard orifice with $C = 0.61$. When the jet re-expands to fill the

tube its appearance becomes turbulent or broomy. (*b*) is a ROUNDED ORIFICE which has a coefficient of discharge varying from 0.61 to 0.99 depending upon the curvature. Even a slight dulling of the edge of a standard orifice increases the discharge several per cent. while if the curvature of the orifice conforms to the direction of the stream lines, the contraction is entirely suppressed and $C_1 = C = 0.96–0.99$. This is an ideal end connection to avoid energy losses. (*c*) is an inward-projecting tube for which $C_1 = C = 0.72$. It is a common type of end connection for a pipe line when no attempt is made to avoid entrance losses. (*d*) is BORDA'S TUBE for which $C = 0.5–0.53$. (*e*) is a conical converging tube, the discharge from which varies with the value of the angle θ: the maximum value of C is 0.94 which occurs when $\theta = 13.5°$. (*f*) is a VENTURI OR COMPOUND TUBE composed of a rounded orifice and an expanding tube with angle of about 10°. Pressure at section AB is less than atmospheric and may be as low as $-$ 24 ft.; the equivalent head is $h + 24$ which gives theoretical values of $C = 8$ or 9 for section AB. Experiments by Francis show C actually to be as high as 2.43. The coefficient for the discharge end is always less than unity.

Loss of head for any pipe, or orifice discharging freely with velocity v under total head h is $h_f = h - v^2/2g$. Loss of head for an orifice or tube whose coefficient of velocity is C_1 is

$$h_f = (1 - C_1^2)h = (1/C_1^2 - 1)v^2/2g.$$

Example. For a standard orifice, $h_f = 0.04h = 0.041v^2/2g = 0.11v_0^2/2g$ where v_0 is the velocity in the plane of the orifice. For a standard short tube (Fig. 46, *a*) $h_f = 0.33h = 0.49v^2/2g$. For an inward-projecting tube (Fig. 46, *c*) $h_f = 0.48h = 0.93v^2/2g$.

Nozzles. Types of nozzle tips are shown in Fig. 47. The SMOOTH NOZZLE is most common. If properly designed there should be no contraction and $C_1 = C = 0.97 - 0.99$. The RING TIP was designed from the mistaken notion that the ring would increase velocity. The coefficient of velocity is the same as for the smooth type while the coefficient of discharge depends on the relative areas of opening and ring. For a SQUARE RING an average value is $C = 0.74$ while an UNDERCUT RING has a value somewhat less. The NEEDLE NOZZLE is designed to regulate flow by moving the needle in and out and has an efficiency of 95 to 98 per cent.; the coefficient of discharge varies from 0.82 to 0.95 being least when the nozzle is nearly closed. Expressions for the velocity and discharge through a nozzle are the same as those for an orifice with velocity of approach, Art. 25.

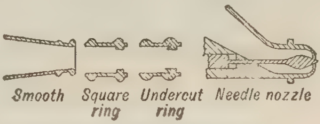

FIG. 47.—Types of nozzles.

Discharge in gallons per minute from a nozzle D in. diameter, attached to a pipe d in. diameter, with the pressure at the base of the tip $= p$ lb. per sq. in. is

$$q = 29.83D^2\sqrt{\frac{p}{(1/C)^2 - (D/d)^4}}.$$

A standard fire stream is one flowing 250 gal. per min. through a $1\frac{1}{8}$-in. smooth nozzle with a pressure at the base of the tip of 45 lb. per sq. in. The hydrant pressure required to throw this stream through 50 ft. of the best rubber-lined hose is 56 lb. per sq. in.; for 200 ft., 77 lb. per sq. in. The pressure drop per 100 ft. of best-quality hose is about 14 lb. per sq. in.; for poor-quality hose it may be double this figure. The best hydrant pressure for fire service is 80 to 100 lb. per sq. in.

Power of a jet discharging W lb. per sec. is $Wv^2/2g = wAv^3/2g$ ft.-lb. per sec., where w = weight of a cu. ft. of fluid, A = cross section of the jet in sq. ft., and v = velocity in ft. per sec. HORSEPOWER $= wAv^3/1100g$. Power of a jet discharging from an orifice or nozzle (coefficient of discharge $= C$ and coefficient of velocity $= C_1$) is $P = CC_1wA\sqrt{2g}\,h^{3/2}$ ft.-lb. per sec. The efficiency of such a jet is $E = C_1^2$.

Example. The respective powers of a standard orifice and standard short tube are $0.58wA\sqrt{2g}\,h^{3/2}$ and $0.55wA\sqrt{2g}\,h^{3/2}$. Corresponding efficiencies are 96 per cent. and 67 per cent. respectively.

Impulse of a jet in a given direction in pounds is $W/g \times$ *change of velocity in that direction*, in which W = lb. of water deflected per sec. If the jet impinges on a flat plate (Fig. 48, a), the impulse is Wv/g lb.; if direction is reversed without loss in friction, the impulse is $2Wv/g$; while for a curved vane, (Fig. 48, c) the impulse in the original direction of jet is $\frac{W}{g}v(1 - \cos\theta)$. If a jet discharging W lb. per sec. (strikes a flat plate moving in the direction of the jet with velocity u, the water that strikes the plate per sec. is $W(v - u)/v$ and the impulse in direction of motion is $W(v - u)^2/vg$. If the jet strikes a series of flat vanes so that all the water discharged strikes some vane, the impulse is $W(v - u)/g$.

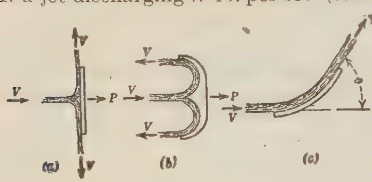

FIG. 48.

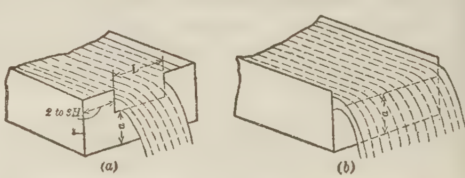
Reaction of a jet issuing from the side of a vessel is $R = Wv/g = wAv^2/g = 2wAh$, in which w = weight per cu. ft. of the fluid, A = cross section of the jet in sq. ft. and h = head on orifice in ft. The reaction is equal to the impulse of the jet on a flat plate and is twice the hydrostatic head. If the jet issues from a standard orifice with coefficient of velocity 0.98 and coefficient of contraction = 0.62, the reaction of the jet on the containing vessel is $R = 1.22wAh$.

27. Weirs

A WEIR is a dam or obstruction placed in an open channel, over which water is caused to flow, or a notch in the side of a vessel through which water flows. If the top or CREST of the weir is a thin plate with a sharp edge, flow is analogous to that through a rectangular orifice with head on the upper edge = zero. If the weir is a rectangular notch with ends $3H$ or more from the walls of the approaching channel, full contraction of the stream is developed and the device is known as a CONTRACTED WEIR (Fig. 49, a). If the length of the weir is the same as that of the approaching channel, so that no contraction takes place at the ends, the weir is called a SUPPRESSED WEIR (Fig. 49, b).



Contracted weir. Suppressed weir.

FIG. 49.

Discharge from a weir. The theoretical discharge is $Q = \frac{2}{3}\sqrt{2g}\,LH$, and the actual, $Q = \frac{2}{3}C\sqrt{2g}\,LH^{3/2}$ in which H is the height above the crest of the weir to the level of still water, L is the length of crest over which water is flowing, and C is a constant which varies slightly with the type of weir and head but has an approximate value of 0.62.

Velocity of approach. It is not always possible to measure the head H to the level of still water on account of velocity in the approaching channel. Mean velocity of approach v_a is found by dividing the discharge by the cross-sec-

tion of the approach channel and the corresponding velocity head $h_v = v_a^2/2g$. The observed head H must be increased by some function of the velocity head giving the general form

$$Q = \tfrac{2}{3}C\sqrt{2g}\,L(H + nh_v)^{3/2},$$

in which n varies from 1.00 to 2.00 depending on the ratio of head to height of crest above the bottom and on the ratio of mean velocity of approach to surface velocity.

Francis formulas. J. B. Francis replaced the expression $\tfrac{2}{3}C\sqrt{2g}$ by the constant 3.33. His formulas for SUPPRESSED WEIRS are $Q = 3.33LH^{3/2}$ and $Q = 3.33[(H + h_v)^{3/2} - h^{3/2}]$. Later investigators prefer the form $Q = 3.33L(H + 1.4h)^{3/2}$.

For CONTRACTED WEIRS Francis decreased the length L by $0.1H$ for each end contraction, making the expression for the ordinary rectangular notch

$$Q = 3.33(L - 0.2H)(H + 1.4h)^{3/2}.$$

The Francis formula is widely used and should give results within 1 to 3 per cent. for carefully constructed SUPPRESSED WEIRS with heads from 0.3 to 2.0 ft.; for $H = 0.2$, increase the discharge 3 per cent. and increase 7 per cent. for $H = 0.1$. If the height of crest a exceeds $4H$ the influence of velocity of approach will cause increase in discharge of 1 per cent. or less, which is negligible in view of other uncertainties. For CONTRACTED WEIRS, which are a little less accurate, velocity of approach is negligible unless the ratio of H to a is abnormally high.

Fig. 50 gives the discharge in cu. ft. per sec. per ft. of length by the Francis formula. To use the scale, find first the approximate discharge, neglecting velocity of approach. Divide this by the area of the approaching channel to get v. Replace H by $H + 1.4v^2/2g$, taking the value of the velocity head from Fig. 50. For CONTRACTED WEIRS replace L by $L - 0.2H$.

Example 1. Find the discharge from a SUPPRESSED WEIR 4 ft. long under a head of 0.625 ft.; crest 2 ft. above the bottom of the channel.

From Fig. 50, the discharge per ft. of length is 1.65, hence $Q = 6.60$. The area of the channel is $4 \times 2.625 = 10.5$ sq. ft., hence $v_a = 0.628$ ft. per sec. and $h_v = 0.0061$. Then $H = 0.625 + 1.4 \times 0.0061 = 0.6335$ and $Q = 6.72$ cu. ft. per sec.

Example 2. A CONTRACTED WEIR is to be designed to discharge 4 cu. ft. per sec.

Either the length or the head may be assumed for purposes of trial. Assuming $H = 0.5$, the discharge per foot of width is 1.18 and the necessary width is $4/1.18 = 3.4$. Adding $0.2H$ for the effect of end contractions the width is 3.5 ft., which lies between $4H$ and $8H$ and hence is satisfactory. End contractions should have a minimum value of 1 ft. each, making the width of channel 5.5 ft. The depth of crest should not be less than 1.5 ft., making the area of the approach channel 11 sq. ft.; velocity of approach, 0.364; and velocity head $h_v = 0.0019$, which is negligible.

Bazin formula. $Q = m\sqrt{2g}\,LH^{3/2}$ where $m = (0.405 - 0.00984 - H)\left[1 - 0.55\left(\dfrac{H}{a - H}\right)^2\right]$ in which a is the height of the crest above the bottom of the approaching channel. This formula needs no correction for velocity of approach and is probably the most accurate for a wide range of heads. It may be used safely for heads between 0.2 and 6.0 ft. For extremely low heads it gives high results.

Measurement of flow by weirs. A weir is the standard device for measurement of moderate flows of water. To get correct results, it must be constructed in a standard manner. The crest must be level and have sharp or square edges. The sheet of water or NAPPE must jump free of the downstream face and allow free access of air to the under side. In SUPPRESSED WEIRS the channel walls should extend beyond the crest to prevent lateral expansion of the nappe. If END CONTRACTIONS are used they should be at least $2H$ and preferably $3H$ or more in length to develop full contraction, and the height of crest a (Fig. 49) should be at least $3H$. It is preferable that the length L be between $4H$ and $8H$ although weirs of 20 ft. or more in length are in common use. The velocity of approach should be low. For a CONTRACTED WEIR the area of the approach channel should be $6LH$ or more, which makes the velocity of ap-

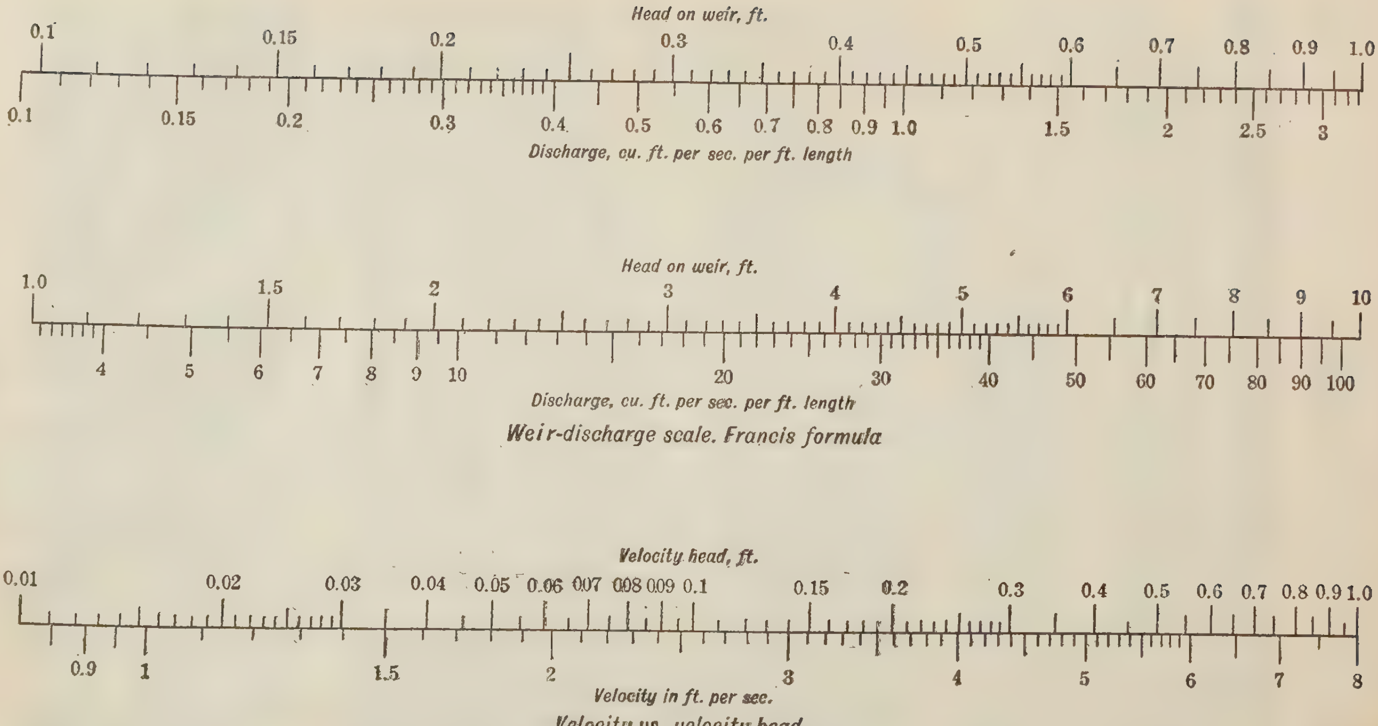


FIG. 50.—Scales for weir calculations.

proach negligible. HEAD should be measured accurately a distance more than $6H$ upstream to eliminate the slope of the surface toward the weir. For approximate work a stake is driven into the channel above the weir with its top level with the crest and head is measured directly by a scale held upon this stake. For more accurate work water is led from the channel to a pail upon which a hook gage is mounted.

Triangular-notch weirs are convenient for measurement of very small to moderate discharges and give good results for heads between 3 and 10 in. DISCHARGE is $Q = \frac{4}{15}c\sqrt{2g}\,LH^{3/2}$ where L is width of notch H ft. above the vertex; $c = 0.60$ for angles at vertex of 90° and 60°. For a 90° weir $L = 2H$ and $Q = 2.53H^{5/2}$ cu. ft. per sec.

Trapezoidal or Cippoletti weir is designed with end slopes of one horizontal to four vertical, which will just compensate for the effect of end contractions. DISCHARGE is then given by the Francis formula $Q = 3.33LH^{3/2}$. Some authorities give $Q = 3.36/LH^{3/2}$.

ROUNDING OF CREST suppresses contraction and increases discharge. INCLINING UPSTREAM FACE with the current increases discharge while sloping the face upstream causes decrease. WIDENING THE CREST so that the nappe no longer jumps free increases friction and reduces discharge.

Dams and spillways may be regarded as weirs; they are by no means accurate as measuring devices.

The coefficient in the Francis formula varies from 2.6 to 4.0 or more depending on the form of dam. For a wide flat-topped dam with width of crest greater than H the coefficient is 2.64 giving discharge 80 per cent. of standard. Rounding the crest to conform to stream lines and inclining the upstream face with the current gives a coefficient of 4.0 or more. For such a dam the discharge varies from 97 to 120 per cent. of standard as the head varies from 0.5 to 4 ft. In designing a waste weir or spillway, the probable flood discharge should be estimated, a large factor of safety introduced, and the dimensions of the weir determined from $Q = MLH^{3/2}$. A common value of M is 3.0.

28. Flow in pipes

When water under pressure flows in a pipe there is a continuous loss of pressure head due to friction between the water and the pipe and internal friction in the water. This condition is shown by Fig. 51, which shows pressure heads necessary in pumping water from (A) to (B). This friction and the corresponding friction head h_f vary widely with the nature and condition of pipe, diameter, and velocity of flow. There is much difficulty in obtaining a satisfactory formula due to the number of variable factors and to the fact that roughness cannot be defined mathematically; also the degree of roughness does not remain constant in service. There are many formulas but all may be placed in one of two classes: (1) friction head is assumed to vary directly as v^2 and inversely as d. $h_f = flv^2/2dg$; the friction factor f is constant for any assumed condition but is varied as v and d vary, l = length in ft., v = velocity in ft. per sec., and d = diameter in ft. (2) $h_f = alv^n/d^r$ in which a is constant and n and r are chosen for average conditions.

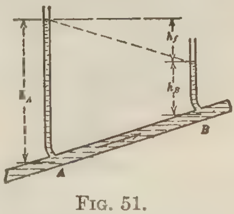

FIG. 51.

Attainable precision. For carefully laid new pipe, a discharge within 10 per cent. of calculated value is all that may be expected. After a few months friction may increase as much as 20 per cent. and in the course of years the diameter may be reduced 50 per cent. by tubercules of iron rust; this deposit forms more rapidly in some waters than others so that each case is a special problem. Friction factors are given for both new and old pipes and in pipe diagrams allowances are made for decrease of capacity with age.

Secondary losses of head are negligible in long pipes but may be a large part of the total loss in pipes of length $50d$ to $500d$. LOSS AT ENTRANCE $= mv^2/2g$ where $m = 1/C_1^2 - 1$,

in which C_1 is the coefficient of velocity for end connection; $m = 1.0$ for inward projecting pipes, 0.5 for square-edged entry with end of pipe flush with the inside of the reservoir wall, and 0 for rounded edge conforming to stream-line flow. Loss DUE TO 90° BENDS is the same as that for straight pipe of length 10 to $20d$, it is smallest when radius $= 3d$; it is greater for large pipes than for small ones, varying approximately as d. Loss DUE TO VALVES is uncertain but equivalent to a length of $6d$ at full gate. Loss DUE TO EXPANSION OF SECTION occurs when water flowing in a small pipe with velocity v_1 suddenly enters a large pipe in which the velocity is v_2; this loss is $h_l = (v_1 - v_2)^2/2g$. It occurs in hydraulic machines, pipes and channels, whenever the section of flowing water is suddenly enlarged; it can be prevented by having the increase gradual as in the Venturi meter (Art. 32). Loss DUE TO SUDDEN CONTRACTION OF SECTION is similar to that at the entrance to square-edged pipe; it depends on the ratio of pipe diameters and has a maximum value of $0.5v^2/2g$, in which v is the velocity in the smaller pipe.

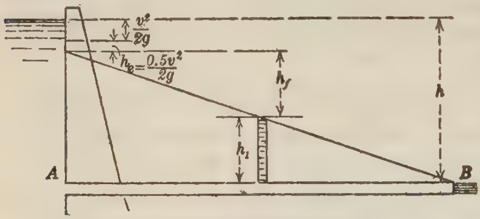

FIG. 52.—Hydraulic gradient, short pipe.

Hydraulic gradient is a line that represents the height of the pressure head at any point in a pipe line. Fig. 52 shows this line for a short horizontal pipe with square-edged entry. The pressure at any point is found from the relation: *pressure head = total head − velocity head − lost head.*

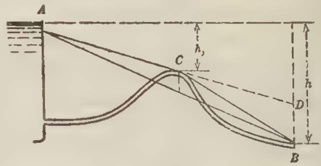

FIG. 53.

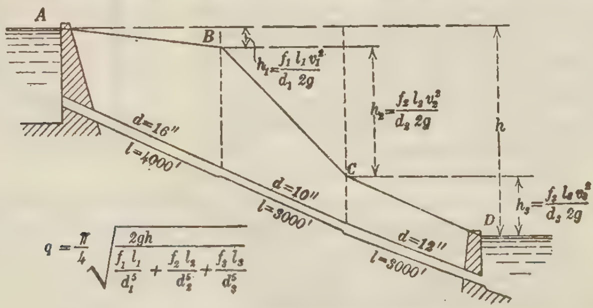
When there is no flow, the head at (B) is h. When free discharge occurs at (B), the drop at (A) = the velocity head $v^2/2g$ plus entrance loss, $h_e = 0.5v^2/2g$; the head then drops uniformly to zero at (B). If the pipe were laid on the hydraulic gradient there would be no pressure head and the slope would be just sufficient to give the required flow.

When a pipe rises above the hydraulic gradient (Fig. 53), negative pressure occurs at (C). If this pressure is less than 25 ft., water will syphon over and discharge at (B) under head h. But it is almost impossible to keep the pipe air tight and air dissolved in the water is liberated under the reduced pressure; hence air collects at (C) and breaks the vacuum.



$$q = \frac{\pi}{4}\sqrt{\frac{2gh}{\frac{f_1 l_1}{d_1^5} + \frac{f_2 l_2}{d_2^5} + \frac{f_3 l_3}{d_3^5}}}$$

FIG. 54.—Hydraulic gradient for compound pipe.

The pipe then discharges at (C) under head h_1; section (CB) acts as a conduit running partly full. This may be avoided by closing a valve at (B) until the hydraulic gradient rises above (C), then opening an air valve at (C). Negative pressure at (C) may be avoided by a compound pipe that makes the hydraulic gradient ACB, Fig. 53. Fig. 54 shows the hydraulic gradient for a long compound pipe in which velocity head and secondary losses have been neglected. If the friction factor f is assumed the same for each pipe, the slope of

the gradient varies as v^2/d and since the discharge q is the same for each section, v varies as l/d^2, hence the slope varies inversely as d^5.

Flow in short pipes. If the loss at entrance is $mv^2/2g$ and loss due to bends, valves, and other secondary causes is $m_1v^2/2g$, then $h - v^2/2g = (m + m_1 + fl/d)v^2/2g$ and $v = \sqrt{2gh}/\sqrt{1 + m + m_1 + fl/d}$. If losses due to valves, bends, etc., are allowed for by using an equivalent length of straight pipe, the velocity and discharge for square-edged entry are

$$v = \sqrt{\frac{2gh}{1.5 + f\frac{l}{d}}}; \quad q = 0.7854d^2\sqrt{\frac{2gh}{1.5 + f\frac{l}{d}}}$$

from which the diameter in feet required for discharge q is

$$d = 0.479(1.5d + fl)^{1/5}(q^2/h)^{1/5}.$$

To solve the equation for diameter, use a trial value of $f = 0.02$ and omit the term $1.5d$ for the first approximation. Use a value of f from Table 26 that corresponds with the approximate value of d and solve again. For very short pipes where $l < 50d$, the coefficient m should be replaced by $1/C_1^2 - 1$ and l by $l - 3d$ hence $v = \sqrt{2gh}/\sqrt{1/C_1^2 + f(l - 3d)/d}$.

Table 26. Friction factors (f) for clean iron pipes

6	0.015	0.014	0.013	0.012	0.011	....	....

Long pipes. Where length exceeds $4000d$, secondary losses and velocity head are omitted and the formulas become

$$v = \left(\frac{2ghd}{fl}\right)^{1/2}; \quad q = 6.3\left(\frac{hd^5}{fl}\right)^{1/2}; \quad d = 0.479\left(\frac{flq^2}{h}\right)^{1/5}.$$

From Darcy's experiments the friction factor $f = 0.02 + 0.00167/d$, where d is in feet, for new clean cast-iron pipe with well-laid joints, and twice this value for old, foul pipe. This value is too high for large cast-iron pipe and wood-stave pipe and too low for riveted steel pipe. Table 26 gives Merriman's values for f for new well laid cast-iron pipe (*Treatise on Hydraulics*, John Wiley & Sons). For OLD PIPE these values should be multiplied by two for diameters of 3 in. or less and by 1.5 for 36 in. or more. Choice of a multiplier is a

matter of judgment. To determine the diameter required for a given discharge, use a trial value of $f = 0.02$ and solve. Then select the value of f that corresponds to the first result and solve again. Pipe-flow diagrams lessen labor and are sufficiently accurate.

Example. Find the diameter required to deliver 7 cu. ft. per sec. through a pipe 5000 ft. long under a head of 25 ft.

TRIAL SOLUTION: $d = 0.479(0.02 \times 5000 \times 7^2 \div 25) = 1.37$ ft., for which $v = 4.7$. The corresponding value of $f = 0.021$, hence $d = 1.39$ ft. or 16.7 in. The commercial size selected should be 16 or 20 in.

Chezy formula is most generally used for investigation of flow in long pipes, channels and conduits. It states that $v = C\sqrt{Rs}$ in which C is a constant, R is the hydraulic radius in ft., and s is the slope of the hydraulic gradient. The formula applies to everything from smooth pipes to turbulent streams.

HYDRAULIC RADIUS OR HYDRAULIC MEAN DEPTH is the section area of the flowing stream divided by the wetted perimeter and is expressed in feet. Velocity and discharge vary with R and are maximum for a given area when R is maximum. If p = wetted perimeter and A = section area, $R = A/p$, hence for circular conduits full or half full $R = d/4$ and for a rectangular flume b ft. wide and d ft. deep $R = bd/(b + 2d)$. SLOPE OF HYDRAULIC GRADIENT is the friction head per unit of length, hence $s = h_f/l$. It is given as feet per 1000 ft., ft. per mile, and as a ratio. The CHEZY CONSTANT, C, varies with R, s and with the nature of the conduit; it is made to embrace a wide variety of conditions. See Tables 27 and 28.

Table 27. Chezy constant (C) for cast-iron pipe

Diameter of pipe, inches	Velocity, in feet per second

72	93	101	105	110
103	114	109	106	104

Discharge of a pipe running full is given by the Chezy formula as $q = \dfrac{C\pi d^2\sqrt{ds}}{8}$; also $d = \left(\dfrac{8q}{\pi c\sqrt{s}}\right)^{2/5}$. The diameter is best found by trial using a tentative value of $C = 125$.

Relation between friction factor and Chezy constant. The Chezy formula applied to pipes under pressure is in the same form as the friction-factor formula for long pipes, $v = \sqrt{2ghd/fl}$. Replacing s by h/l and R by $d/4$, $v = C\sqrt{dh/4l}$. Equating these two values of v, there results $f = 8g/C^2$.

Pipe-flow diagrams. Fig. 55 (*U. S. Reclamation Service*), shows the relation between discharge, friction head, velocity, and diameter; if any two are known the other two may be determined.

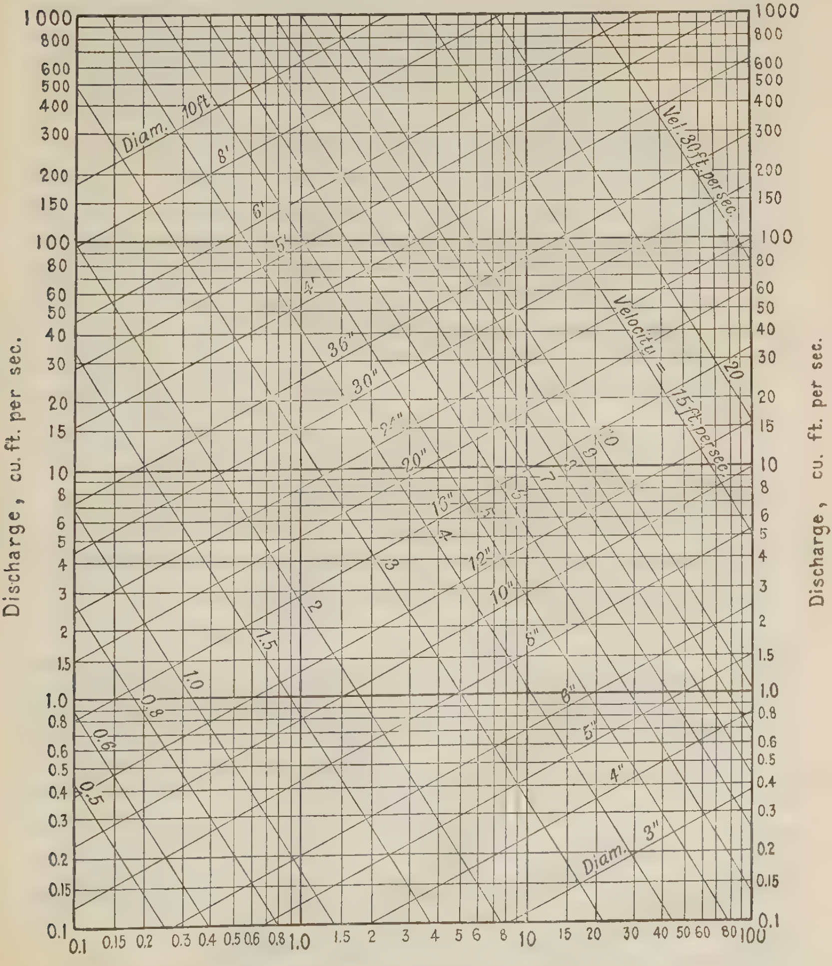

FIG. 55.—Pipe flow, U. S. Reclamation Service formula.

The diagram is based on the formula $h_f = 0.38v^{1.86}/d^{1.25}$ in which h_f is friction head per 1000 ft. of length. The constant and the exponents of v and d are based on average results of a large number of experiments; results agree quite closely with those obtained by use of Tables 27 and 28, and with values found by Kutter's coefficient $n = 0.011$ (Art. 30). Results are for cast-iron and wrought-iron pipe in good condition; for OLD PIPE in service 10 years or more and for riveted-steel pipe, the friction head should be multiplied by 1.45 to 1.63 and discharge divided by 1.20 to 1.28 for velocities of 2 to 5 ft. per sec. For this case the formula is $h_f = 0.50v^2/d^{1.25}$.

Example. New pipe two miles long is to discharge 10 cu. ft. per sec. with drop of head of 40 ft., what diameter is required?

$s = 40/10{,}560 = 0.00379$ or 3.79 ft. per 1000 ft. Enter the diagram on the vertical line representing 3.79 ft. per 1000; at intersection with the horizontal line representing 10 cu. ft.

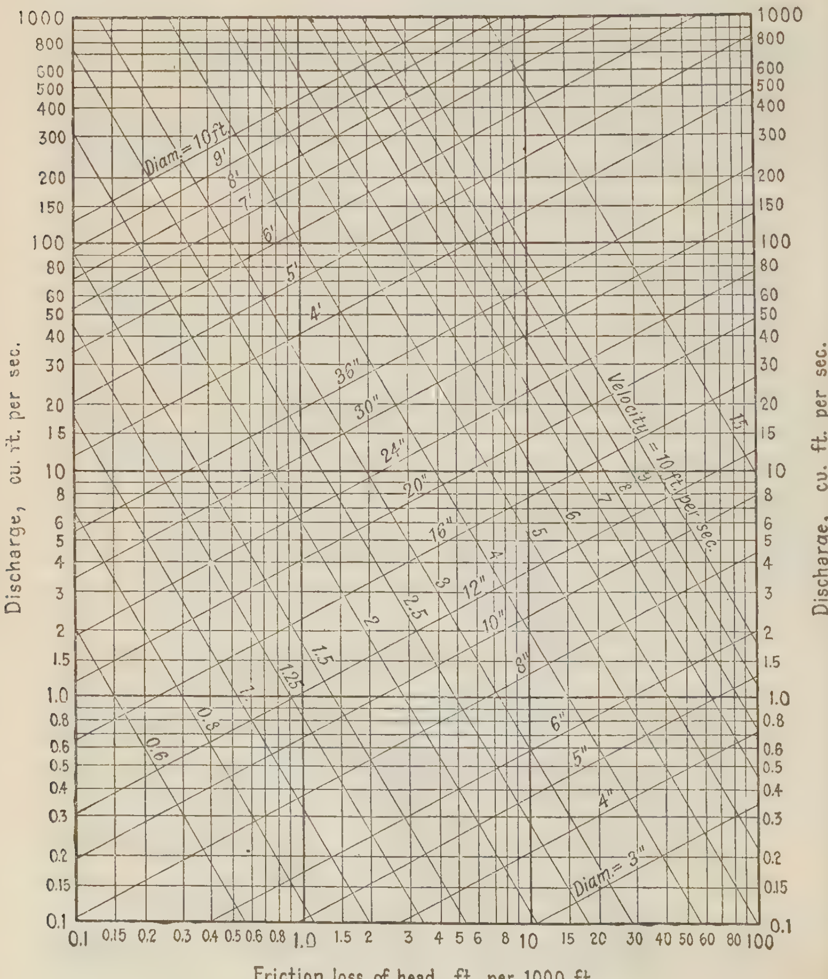

FIG. 56.—Pipe flow, Hazen-Williams formula (*after Bleich*).

per sec. read 20-in. pipe required. If the pipe is to remain in service 10 years or more, divide discharge by 1.25; 20-in. pipe gives $10.8 \div 1.25 = 8.65$ cu. ft. per sec. and 24-in. pipe gives 13.6 cu. ft. per sec.

Hazen-Williams formula, $v = 1.318\, CR^{0.63}s^{0.54}$ is based on average results.

The constant 1.318 is introduced to make the coefficient C approximately the same as in the Chezy formula. Hazen and Williams values for C are: best cast-iron pipe, 140; good new cast-iron pipe, 130; tuberculated pipe, 80 to 110; for DESIGN of cast-iron pipe lines, 100; new riveted-steel pipe, 110, ordinary wrought-iron pipe, 100; lead, brass, tin pipe, 140; smooth wood pipe, 120; vitrified pipe, 110; smooth clean masonry, 140; slime-coated masonry, 130; ordinary masonry, 120; brick sewers, 100. Application is much simplified by use of Fig. 56 (S. D. Bleich). The diagram is constructed for $C = 100$; for any other value of C, multiply velocity and discharge by $c/100$. To SELECT PIPE to give discharge q, multiply q b y $100/C$ giving q^1, and using this value find d from the diagram. To get ACTUAL VELOCITY, multiply the diagram value by $C/100$. For CHANNELS, multiply the hydraulic radius by 4 to get the equivalent diameter.

Example. Find the diameter of riveted-steel pipe to carry 40 cu. ft. per sec. with slope $s = 1.001$. $C = 110$. Multiply 40 by 100/110, then $q^1 = 36.36$ and $d = 46$ in. The corresponding velocity is 3.2, but since the actual discharge is 40, actual velocity is $3.2 \times 110/100 = 3.52$ ft. per sec.

Comparison of U. S. Reclamation Service and Hazen-Williams formulas. F. W. Schoder (*Marks*) states that Fig. 55 gives discharges that are slightly too great for new pipe and hence may be used safely for design when the pipe is to remain in service 5 to 10 years, if the velocity is sufficient to prevent sedimentation and the water is not highly corrosive. But these values correspond to the friction factors for new pipe (Tables 27 and 28) and to values of C in Hazen-Williams formula as follows: 6-in. pipe, 120; 12-in. pipe, 127; 24-in. pipe, 130; 10-ft. pipe, 140. These are coefficients for new cast-iron pipe and pipe in best condition, hence Fig. 56 is more conservative than Fig. 55, but the latter probably gives a closer indication of discharge of a pipe in fairly good condition. Hazen-Williams formula can be used for any class of pipe by choosing the proper value of C.

Compound pipe. A pipe line is to be made of sections of different diameters, the same discharge flowing through all; required to find the discharge.

Solution. $h = \dfrac{f_1 l_1 V_1^2}{2gd_1} + \dfrac{f_2 l_2 V_2^2}{2gd_2} + \dfrac{f_3 l_3 V_3^2}{2gd_3}$, which shows that friction head for each section varies approximately as l/d^5. From this relation friction heads may be found by trial such that each section gives the same discharge. In Fig. 54 let the diameters be 16 in., 10 in., and 12 in., and the lengths 4000 ft., 3000 ft., and 3000 ft., and let the total head be 120 ft. Friction heads for the sections vary as $4000/16^5 : 3000/10^5 : 3000/12^5$, or as 3.8 : 30 : 12. Hence the respective heads are $120 \times 3.8/45.8$, $120 \times 30/45.8$, $120 \times 12/45.8$ or 9.95 ft. 78.6 ft., and 31.4 ft. Fig. 55 shows that each section will discharge 4.4 cu. ft. per sec. under these heads.

Branching pipe. To design branching pipe (Fig. 57) to discharge given amounts at C and D assume a pressure drop from (A) to (B) and design the section $(A - B)$ for a discharge equal to the sum of those required at (C) and (D). Then design sections $(B–C)$ and $(B–D)$ to give the desired discharge under their respective heads. If the diameter of any section is fixed, all pressure drops are fixed and no assumptions are necessary.

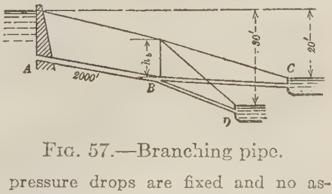

FIG. 57.—Branching pipe.

Example. Find the diameters required to discharge 10 cu. ft. per sec. at (C) and 5 cu. ft. per sec. at (D). Assuming a drop of 10 ft. from (A) to (B), section $(A–B)$ must discharge 15 cu. ft. per sec. under 10 ft. head or 5 ft. per 1000 ft. From Fig. 55 d lies between 20 and 24 in. Assuming the latter, the drop is 6 ft., leaving heads on (C) and (D) of 14 and 24 ft. respectively. $(B–C)$ is then between 16 and 20 in., and $(B–D)$ between 10 and 12 in. It is best to select the larger diameters and control the discharge by gate valves.

To find the discharge from an existing pipe line, make a series of trials assuming different drops from (A) to (B) until one is found that gives a flow through $(A–B)$ that equals the

sum of those through (B–C) and (B–D). If, in Fig. 57, the diameter of (A–B) is 30 in., (B–C) 24 in., and (B–D) 16 in., assuming 10-ft. drop from (A) to (B), the discharges are: (A–B), 33 cu. ft. per sec.; (B–C), 20; and B–D, 14.

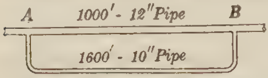

Fig. 58.—Looped pipe.

Looped pipe (Fig. 58). Discharge from each branch is found from the fact that the pressure drop from (A) to (B) is the same in each.

Example. Find the pressure difference from (A) to (B) to give a flow of 5 cu. ft. per sec. and find the flow through each pipe.

For the same friction head, the discharge q varies as $(d^5/l)^{1/2}$, approximately. Hence the ratio of discharges is $\left(\frac{12^5}{1000}\right)^{1/2} : \left(\frac{10^5}{1600}\right) = 15.7 : 7.75$ or nearly $2 : 1$, which gives values of 3.33 and 1.67 cu. ft. per sec. for the two branches. The corresponding lost heads are 6 and 5.8 ft. (Fig. 55). A head of 5.9 ft. will give discharges of 3.2 and 1.8 cu. ft. per sec., as required.

Pump pipe lines. The general problem is selection of pipe for the greatest economy. The pumping head is the sum of the static head and the friction head, the latter varying as d^5 for constant discharge.

Example. Let the pump supply a reservoir with 600 gal. per min. against a static head of 60 ft. through a pipe 2400 ft. long. Valves and bends increase the equivalent length to 2500 ft. Select the pipe.

$q = 1.335$ cu. ft. per sec. The head lost per 1000 ft. for this discharge is approximately 1, 2.5, 7.2, and 30 ft. for diameters of 12, 10, 8 and 6 in. respectively (Fig. 55). Pipes 6-in. or less diameter give too large friction loss. The total losses for 8-, 10- and 12-in. pipes are 17.5, 6.25, and 2.5 ft. to which the static head must be added to find the pump pressure. The most economical pipe will be the one for which the interest on first cost of pipe line plus the value of power lost in friction will be a minimum. Note that a small change in diameter makes a large difference in friction head.

Pumping. Three cases are represented in Fig. 59. (a) The total head is the static head plus friction head and the net power required is $WH/550$ hp., where W = pounds pumped per sec. and H is total head. (b) The pumping head is the difference between the friction and static heads. The negative head at (C) should not be greater than 25 ft. Since the slope of the hydraulic gradient varies inversely as d^5 it is possible to control the pressure at (C) by a proper selection of pipe diameter. (c) The pipe is arranged to eliminate negative head at (C). The static head is the difference in elevation between (A) and (C) and the friction head is the pressure drop from (A) to (C). Pipe (CB) is a conduit designed to carry the given discharge under head h. Its diameter is less than that of the line (AC).

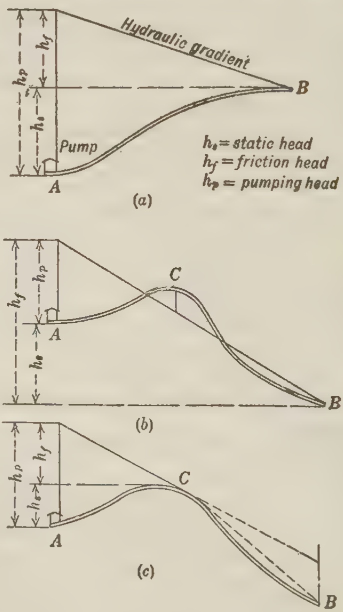

Fig. 59.—Pump pipe lines.

Example. (AC) = 2000 ft., (CB) = 4000 ft.; elevation of (A) = 20 ft., (C) = 50 ft., (B) = 0. Find the power required to pump 4 cu. ft. per sec. through 12-in. pipe. (b) Fig. 55 gives h = 7.9 ft. per 1000 ft. = 47.4 ft. Static head = − 20 ft. hence the pumping head = 27.4 ft. and Hp. = 12.45 net. (c) If no negative pressure at (C) is permissible, the pumping head becomes $30 + (2 \times 7.9) = 45.8$ ft. and (CB) is designed to discharge 4 cu. ft.

per sec. under a head of 50 ft. The diameter lies between 10 and 12 in. hence the 12-in. pipe will run partly full. This can be avoided by partially closing a gate valve at (B). Were the section (AC) made of 16-in. pipe, the friction head per 1000 ft. becomes 1.9 ft., making the pumping head 33.8 ft., a saving of 26.6 per cent.

Power delivered by a pipe is proportional to the product of the discharge and head at the delivery end. In Fig. 60, h_1 is a maximum when $q = 0$ and $h_1 = 0$ when q = maximum. Power varies as $q(h_1 + v^2/2g)$ and has a maximum value when one-third of the static head is consumed in friction. Usually the value of the power is such that the pipe-line is designed to consume but 5 to 10 per cent. of the total head in friction. Selection of a proper pipe diameter is governed by the same factors that control in pump pipe lines. Fig. 61 shows relations between head, power, and discharge for pipe delivering power.

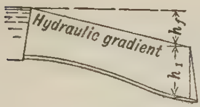

Fig. 60.—Pipe with nozzle delivering power.

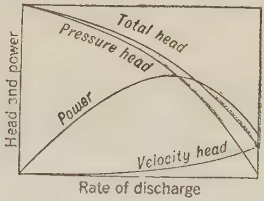

Fig. 61.—Head in pipe and power delivered.

Example. Water under a total head of 1000 ft. is brought to a 1000-kw. Pelton wheel by a pipe 5000 ft. long. The efficiency of the wheel is 85 per cent. Design a pipe so that the friction loss shall be about 10 per cent. of the total head.

Assuming the head on the wheel = 900 ft., $q = 1000 \times 550/(900 \times 62.5 \times 0.746 \times 0.85) = 15.5$ cu. ft. per sec. For cast-iron pipe in good condition, a 120-ft. head is required to discharge this quantity through 16-in. pipe and 40-ft. for 20-in. pipe (Fig. 55). 16-in. pipe will supply 16 cu. ft. per sec. with a loss of 125 ft. or 12.5 per cent., which is the amount required to give 1000 kw. under 875-ft. head, while 20-in. pipe will give the same power with a loss of 3.5 per cent., the discharge being 14.5 cu. ft. per sec. After 10 to 15 years' service the 20-in. pipe will maintain the required power with a loss of 6 per cent. and discharge of 15 cu. ft. per sec. (Fig. 56 with $C = 100$.)

Water hammer or ram is the shock or blow produced by the dynamic action of water when the flow is suddenly checked by the rapid closing of a valve or by other obstruction. The sudden decrease in velocity sets up a pressure wave which produces a maximum excess pressure of $p = 63v$ lb. per sq. in. where v = change in velocity or "extinguished" velocity; the SPEED OF PROPAGATION is about 4500 ft. per sec. If the time of closing the valve exceeds 0.0004281 sec., $p = 0.0271v/t$. If the pressure wave enters a branch pipe with a dead end, the excess pressure may be increased two- or three-fold; a series of branches may build up a dangerous pressure.

When the velocity in a long pipe supplying power to a water wheel is suddenly checked a pressure wave is built up which travels back to the reservoir and, due to the elasticity of water and pipe, forces water back, thus producing a wave of reduced pressure. The result is establishment of an oscillating wave with gradually decreasing amplitude and period depending on the length of pipe. Water hammer may be greatly reduced by the use of air chambers on pumps and of surge tanks on pipe lines supplying water wheels; automatic relief valves employing springs are not as good. Velocity should never be checked suddenly hence the valves are designed to close slowly. Allowance should be made for water hammer in design of pipe.

29. Design of pipe

Determination of diameter usually involves selection of a standard size of pipe that will furnish the required discharge under given conditions. Dia-

grams for selection of diameter give as great accuracy as conditions warrant. The roughness factor is so uncertain that discrepancies of 10 per cent. or more between calculated and actual discharge may be expected.

Cast-iron pipe. Standard sizes are given in Table 29. Bell-and-spigot (Fig. 62) or flanged joints are provided. Flanged pipe is required for pump connections and for conditions where it may be desired to remove a section. Exposed pipe is generally flanged and submerged pipe of bell-and-spigot variety.

Table 29. Standard weights and thicknesses of cast-iron bell-and-spigot pipe

Fig. 62.

Fig. 63.

The latter is made tight by calking and then pouring in a lead collar which is afterwards calked. Special flexible lead joints (Fig. 63) are made which are capable of motion of several degrees without causing leakage. Joints allow for change in length due to temperature change, hence no temperature stresses are produced.

Thickness of cast-iron pipe is given by Brackett's formula,

$$T = 0.25 + (P + P^1)r/3300,$$

in which T = thickness in inches, P = maximum static pressure in lb. per sq. in. P^1 = allowance for water hammer and r = radius in inches. This formula allows a large factor of safety to cover inequalities in casting and strains other than that due to internal pressure

and gives sufficient thickness to insure the pipe against excessive breakage in handling and shipping. For large pipe the value of $P^1 = 70$ lb. per sq. in.; for smaller pipe Brackett gives the following:

Diameter of pipe, inches.	36	30	24	20	16	12	10 to 3
P^1, pounds per square inch.	75	80	85	90	100	110	120

In ordering pipe for given pressure or head, refer to makers' tables.

Coating. Cast-iron pipe is always given a protective coating by dipping in a solution of coal tar and linseed oil at 300° F.

Pipe is subject to formation of tubercles of RUST, especially if the water contains much CO_2. These deposits may greatly reduce the diameter in the course of years hence suitable allowance must be made. Hazen-Williams formula with $C = 100$ (Art. 28, Fig. 56) allows a considerable factor of safety and should give the correct discharge after 16 years' use, if corrosion is not abnormal. Cast-iron pipe should have a LIFE of 40 to 80 years. Pipe is sold by the net ton; PRICE varies with the price of pig iron. The price for the pre-war period averaged \$25–\$30 per ton with an average of \$60 per ton for special shapes as *Y*'s, *T*'s, curves, etc.

Wrought-iron and steel lap- and butt-welded pipe is used for distribution of water, gas, and steam in sizes ⅛ in. to 15 in. nominal diameter and in three weights, standard full-weight, extra-strong, and double extra-strong. Special pipe for hydraulic machinery capable of withstanding internal pressure of 10,000 lb. per sq. in. is made by boring solid steel forgings. Most lap- and butt-welded pipe now on the market is mild steel but is often sold as wrought-iron. Large lap-welded steel pipe can be furnished in any diameter in thickness from ⅛ to 1¼ in. Forged flanges and connections are furnished in all sizes. Standard sizes are given in Table 30.

Flow through wrought-iron and steel pipe should be calculated for the actual internal diameter, which differs considerably from the nominal diameter. Small pipe is generally employed in short lengths with many elbows, valves, and other fittings, hence secondary losses of head play an important part. Table 31 gives dimensions of small sizes of standard full-weight pipe and the flow that may be expected for given pressures and equivalent lengths. (Williams and Hazen, *Hydraulic Tables*, Wiley.)

Riveted-steel pipe is used for high pressures and for long mains 30 in. or more in diameter; it is not generally used in smaller sizes. It is cheaper than cast-iron for large diameters. The pipe is made of sheets, 7 or 8 ft. wide, which are bent around and riveted with a double-riveted lap joint. (Butt joints with straps on the outside have also been used.) End joints are made by single-riveting in and out courses, alternate rings being larger and smaller. The pipe is also made in taper lengths, one end designed to slip into the large end of the next length. Continuous riveting is generally used on pipe lines, each length being securely riveted to the next. The pipe must then withstand temperature stresses which, under most unfavorable conditions, may be as high as 9000 lb. per sq. in. Strong anchorages must be provided to withstand the resultant thrust due to temperature change and especially designed valves and fittings must be employed to resist this pressure. Temperature stresses may be avoided by the use of expansion joints. Riveted pipe is also furnished in lengths up to 40 ft. with pressed or forged-steel flanges which bolt together as in cast-iron pipe.

Spiral-riveted pipe is furnished in diameters up to 40 in. Each length is made of single sheet wound with overlapping edges which form a single-riveted spiral seam of great strength. Spiral-riveted pipe is stronger than straight riveted pipe of the same weight and thickness and, due to spiral seams, has more resistance to bending or transverse loading. End connections (Fig. 64)

are of flanged, bolted or slip-joint type. The latter, used for low pressures, consists of a sleeve wrapped in burlap soaked in red lead or tar and driven into the adjoining pipe. Lugs on the pipe are then connected by wire. See also Sec. 23, Table 14.

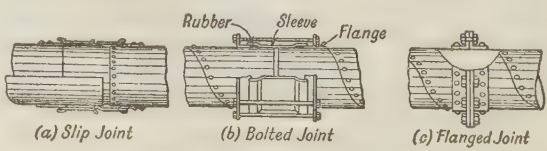

FIG. 64.—Joints for riveted pipe.

Lock-bar pipe (Fig. 65) is made by upsetting the edges of steel plates and inserting them in grooves of a lock bar of H section which is then forced down

over them by hydraulic pressure. The resulting joint has an efficiency of 100 per cent. in place of 72 per cent. for a double-riveted seam, but the joint is usually figured for 90 per cent. efficiency. Carrying capacity is greater than riveted pipe on account of absence of rivet heads.

Fig. 65.—Lock bar for steel pipe.

Coating. Steel pipe has a shorter life than cast-iron pipe and is liable to rust and pitting. It is therefore dipped in hot asphalt solution or is galvanized, which both protects the pipe and renders the joints tighter after calking.

Carrying capacity of steel pipe. Riveted pipe has a rough interior due to projecting rivet heads; these cause eddy currents and increase pipe friction. It carries 10 to 15 per cent. less water than cast-iron or lock-bar pipe. Hazen-Williams formula with $C = 110$ may be used for new pipe and $C = 95$ for pipe in service several years. Values of Chezy constant for new and old pipe are given in Table 27.

Thickness of steel pipe $= \dfrac{\textit{diam. in inches} \times \textit{pounds pressure.}}{2 \times 16{,}000 \times \textit{efficiency of joint}}$ A working stress of 16,000 lb. per sq. in. gives a factor of safety of 3.5. The efficiency of a single-riveted joint a 55 per cent.; double-riveted lap joint, 72 per cent.; lock-bar, 90 per cent. Due allowsince must be made for water hammer and deterioration.

Wood-stave pipe is much used in localities where lumber is cheap and steel and concrete difficult to obtain. It is usually built with diameter greater than 24 in. and for pressure heads of 20 to 250 ft. The pressure should be sufficient to keep the wood saturated. Continuous wood-stave pipe is built in place, the lower half being assembled in a cradle and the upper half assembled over a pipe ring. Staves break joints and end connections are made water-tight by the use of a steel tongue which fits into saw kerfs in each stave. Staves are held together by steel bands; these are not tightened until the wood is thoroughly saturated. Staves are from $1\frac{1}{4}$ to $2\frac{1}{2}$ in. thick and 6 to 8 in. wide. They are cut with true cylindrical surfaces and radial edges. Bands are $\frac{3}{8}$ to $\frac{3}{4}$ in. diameter and are designed and spaced to carry total hoop tension due to pressure in addition to swelling pressure of the wood. This latter may be assumed at 100 lb. per sq. in. Machine-banded pipe is cut and banded in the shop and pipe lengths are joined with standard cast-iron or special fittings. Staves are made with tongues and grooves and banding is a continuous wire wound on under high tension. Flat bands are also used.

Advantages of wood-stave pipe are ease of transport, easy curves made without special fittings, high carrying capacity, relative cheapness and durability. Kutter, $n = 0.009$ to 0.011; Hazen-Williams, $C = 120$.

Reinforced-concrete pipe comes in diameters of 2 to 10 ft. and lengths of 3 to 5 ft. Large diameters are generally poured in place. The pipe is usually reinforced longitudinally with steel bars and transversely with spiral wire, wire mesh, or steel bands, to resist the total hoop tension. When the pipe is not poured in place, longitudinal reinforcement is designed to provide interlocking of adjacent sections so that when the cement joint is made a continuous pipe results. Reinforced-concrete pipe is usually employed for conduits and for pipe under low heads although reinforcement can be designed for any desired pressure. Thickness of concrete averages one inch per foot of diameter, being slightly greater for small sizes.

30. Flow in open channels

Open channels include flumes, conduits, canals, rivers, and closed pipes when the latter flow partly full. FRICTION HEAD appears as a drop in water surface, not as a loss of pressure; the drop in a given length is just equal to the head required to produce flow through that length. The condition is analogous to that of a pipe line laid on its hydraulic gradient. Flow in existing channels is measured directly when possible; in designing channels and in determining flow where direct measurement is impracticable the Chezy formula $v = C\sqrt{RS}$ is used. Values of C for a wide range of conditions are given in KUTTER'S FORMULA,

$$C = \frac{41.6 + \left(\frac{0.0028}{S}\right) + \left(\frac{1.81}{n}\right)}{1 + \left(41.6 + \frac{0.0028}{S}\right)\left(\frac{n}{\sqrt{R}}\right)},$$

and BAZIN'S FORMULA,

$$C = \frac{158}{1 + N/\sqrt{R}}.$$

Values of C depend in both cases on the roughness of the channel and on the hydraulic radius R; Kutter also introduces the slope S. His formula is most used in this country.

Value of coefficient of roughness in Kutter and Bazin formulas

CHANNELS OF UNIFORM SECTION	Kutter, n	Bazin, N
Well-planed timber, evenly laid	0.009	
Neat cement; best pipe	0.010	0.11
Cement, one-third sand; smooth pipe	0.011	
Unplaned timber; ordinary pipe	0.012	
Ashlar; brick work; new sewer pipe	0.013	0.29
Ordinary brick work and sewers; foul pipe	0.015	
Rubble masonry; rough concrete	0.017	0.83
CHANNELS OF NON-UNIFORM SECTION		
Canals in firm gravel, section nearly uniform	0.02	1.54
Earth canals and rivers free from large stones and weeds	0.025	2.35
Canals and rivers in bad order	0.03–0.04	3.2

Limitations of Kutter's formula. Since the formula was designed to cover a wide range of conditions, considerable error is to be expected. For hydraulic radii greater than 10 ft., for velocities greater than 10 ft. per sec., and for slopes less than 0.0001, the formula should be used with caution. If the slope exceeds 0.001, the value of C for $S = 0.001$ may be used with an error less than the probable error from the formula. Great refinement is unnecessary since an error of 0.001 in the selection of the roughness coefficient n may change C 5 to 17 per cent. The value of the formula depends largely on the proper selection of coefficient n; for smooth flumes and conduits, cleaned periodically, an error of 5 per cent. is to be expected; for canals and rivers in bad order, the formula is but a rough approximation.

Open-channel flow diagrams greatly facilitate the use of Kutter's complicated formula. Tables are also prepared giving values of C for all values of R, S and n found in ordinary practice. One of the best diagrams, prepared by Kennison, is given by Fig. 66.

To find velocity when the hydraulic radius, slope and roughness coefficient are known enter the lower part of the diagram on the horizontal line representing the value of R,

follow this line to the intersection with the given value of n, thence vertically to intersection with the assigned slope line; a horizontal line through this latter intersection determines the velocity.

Example 1. Given $R = 3$ ft., $n = 0.015$, $S = 0.0005$, find velocity. Enter at $R = 3$, proceed to intersection with $n = 0.015$. Project vertically from this point to line $S = 0.0005$ (marked 0.5). This point is on the horizontal line $v = 4.7$, which is the result required.

Example 2. An unplaned timber flume 2 ft. wide and 1 ft. deep is required to supply 10 cu. ft. per sec. What slope is necessary? $v = q/a = 5$ ft. per sec. $R = 2/4 = 0.5$ ft.;

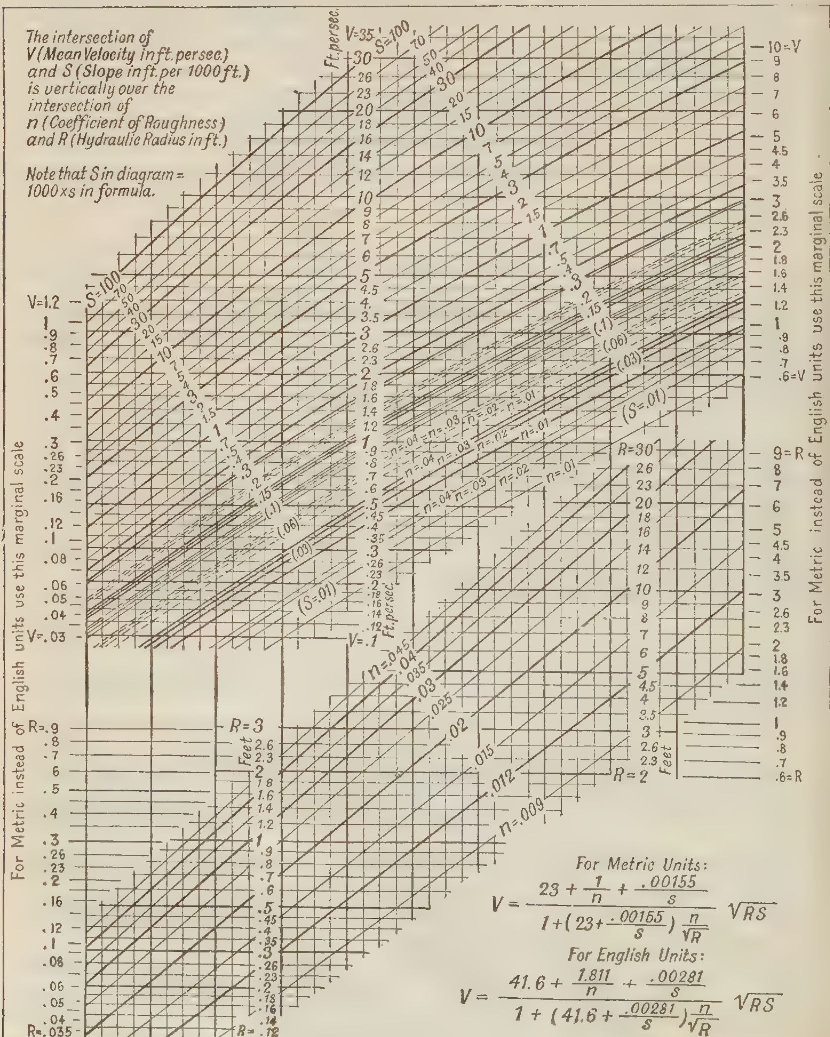

FIG. 66.—Diagram for Kutter formula (*after Kennison*)

n for unplaned timber = 0.012. Vertical from intersection of $R = 0.5$ and $n = 0.012$ intersects line $v = 5$ on line $S = 0.006$ (marked 6) which is the necessary slope. For small values of S, as 0.00001, the position of the line representing S varies with the value of n.

Design of open channels. The Chezy formula shows that velocity increases as R increases. The constant C also increases with R, so that v varies nearly as $R^{2/3}$. Hence for a given discharge, that cross-section should be used which makes R maximum. This condition also makes the perimeter and area of the channel a minimum. A SEMI-CIRCLE meets these requirements hence a semi-circular channel will discharge more water than any other form, for given values of area, slope, and degree of roughness.

Figure 67 shows the channels having the most advantageous elements. The depth of a RECTANGULAR FLUME should be one-half the breadth. This gives the least value of perimeter p hence the least cost for the flume and also the least area for given discharge, hence the least cost for excavation. The best TRAPEZOIDAL SECTION is one-half hexagon. If the side slopes are fixed by the nature of the soil, they should be tangent to a circle of radius d as in Fig. 67. The foregoing sections are not used for UNLINED DITCHES because a shallow ditch is cheaper to dig and maintain. AVERAGE DEPTH is $d = 0.5\sqrt{A}$ where d = depth in ft. and A = area in sq. ft. SIDE SLOPES depend on the material; usual values are 1 : 1, 1.5 : 1, and 2 : 1. For average loam use 1.5 : 1 (Fig. 67).

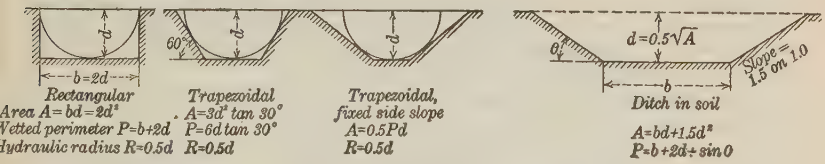

FIG. 67.—Best cross-sections for channels.

Velocity of water should be great enough to prevent deposits of silt and growth of weeds but should not be sufficient to erode the bottom of the channel; 2 ft. per sec. will prevent deposits. The following values of mean velocity are safe against erosion (*Peele*):

Very light loose sand	1.0 to 1.5	Conglomerate, cemented gravel, soft rock	6.0 to 8.0
Average sandy soil	2.0 to 2.5	Hard rock	10.0 to 15.0
Average loam or alluvial soil	2.75 to 3.0	Concrete, water carrying coarse sand	7.0 to 12.0
Stiff clay or ordinary gravel	4.0 to 5.0	Concrete, water carrying fine sand	15.0 to 20.0
Coarse gravel, cobbles	5.0 to 6.0		

The usual velocity for ditches is 2 to 3 ft. per sec., which requires a slope of 3 to 7 ft. per mile. If the available slope is greater than this, the ditch must be lined or else a series of vertical drops introduced. These drops may be wooden or concrete weirs or ramps. The ROUGHNESS COEFFICIENT for unlined earth ditches is usually taken $n = 0.0025$.

Seepage losses in earth ditches may be as high as 25 per cent.; they may be reduced or almost eliminated by linings, which also permit greater velocity and prevent weed growth. LININGS may be puddled clay, road asphalt, or 2 to 4 in. of concrete, placed in position without forms on slopes 1:1 or less. Concrete practically eliminates seepage.

Uniform cross-section is desirable; any change in section causes loss of head by impact and reduces flow. A smooth channel with small changes in section should be regarded as a rough channel in selecting a coefficient of roughness.

Example 1. Design an unplaned timber flume to deliver 20 cu. ft. per sec. with a slope of 0.001.

For the most economic section, $b = 2d$, $A = 2d^2$, $R = 0.5d$, $n = 0.012$. Use Fig. 66 with trial values of d; for values of $d = 1.5$, 1.6, and 1.7 the velocities are 3.3, 3.5, 3.6, giving discharges of 15, 17.8, and 20.8 cu. ft. per sec. Therefore a flume 17 × 34 in. will give the desired flow.

Example 2. Design a ditch in average soil with end slopes 1.5 : 1 to discharge 100 cu. ft. per sec.

Assuming safe velocity = 2.5 ft. per sec., the area must be 40 sq. ft. $d = 0.5\sqrt{A}$, $= 3.2$ ft.; $A = bd + 1.5d^2$, hence $b = 7.7$ ft. Wetted Perimeter $P = b\frac{2d}{\sin\theta} = 19.16$ ft. $R = A/p = 2.09$ ft. Required slope (Fig. 66), is $S = 0.0007$ or 3.7 ft. per mile.

31. Gaging flow in channels

A weir should be constructed for SMALL STREAMS. If a weir or dam does not exist and construction is not feasible, velocity is generally measured by use of FLOATS or by a CURRENT METER. Calculation based on the Chezy formula involves measurement of minute differences of elevation and arbitrary choice of roughness coefficients, hence this method is not recommended unless all others fail.

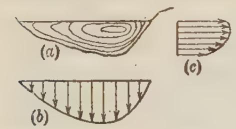

FIG. 68.—Distribution of velocity in stream channel.

Distribution of velocity. Velocity is least at the sides and bottom of the channel and maximum at the deepest part a little below the surface. (Fig. 68.) (*a*) shows contours of equal velocity, (*b*) shows velocity variation in a horizontal plane, (*c*) shows the corresponding curve for a vertical plane passing through the point of maximum velocity. The MEAN VELOCITY, $v = q/A$, is the average of the velocities of all small filaments in the cross-section.

Stream gaging. To measure the discharge directly the velocity must be determined at many points. Plot the transverse profile of the stream bed and divide it into a series of small areas (Fig. 69). Calculate the area and measure the mean velocity for each section. If the areas are $A_1, A_2, A_3, \ldots$, and the corresponding velocities $v_1, v_2, v_3, \ldots$, discharge $q = A_1v_1 + A_2v_2$, etc.

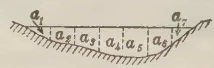

FIG. 69.

SURFACE FLOATS are used for rough field work. The time of passage over a given course is observed and the average velocity taken as 0.8 times the maximum surface velocity. The average velocity in any vertical is 0.86 times its surface velocity. These figures are subject to much variation; the mean velocity may be 90 to 95 per cent. of the surface velocity, hence surface floats are valuable chiefly as a check on other methods and may be 10 to 20 per cent. in error. ROD FLOATS are wooden sticks weighted on one end, or hollow tin cylinders loaded at one end with sand so as to float vertically, nearly touching the bottom and projecting about 6 in. above the surface. Rod floats are very accurate in a channel of uniform cross-section, *e.g.*, a lined conduit. If the float nearly touches bottom its velocity will be average for a given vertical. If the section area is divided into small areas and the velocity of each found by a rod float, the discharge may be found with an error of 5 per cent. or less, but this requires nearly uniform cross-section. Float measurements are laborious and have the added objection that it is often difficult to find any considerable stretch of stream that has approximately uniform section area.

The best method of measurement, aside from a weir, is by CURRENT METER (Art. 32). The U. S. G. S. gives the following four methods of procedure:

(1) Measure velocity at equal intervals of 10 to 20 per cent. of the depth in any vertical, plot the vertical velocity curve, and obtain the average velocity graphically.

(2) Measure velocity at 0.2 and 0.8 times depth and average these results for the mean velocity.

(3) Measure velocity at 0.6 times depth and consider this the mean velocity.

(4) Measure velocity 0.5 to 1 ft. below the surface and multiply by a factor ranging from 0.78 to 0.98, using 0.85 to 0.90 for ordinary stages of flow.

Method (1) should be adopted for precise work. Methods (2) and (3) are based on the assumption that velocity distribution is normal and that the velocity curve is a parabola. Experimental results justify these general assumptions; if, in a given case, the velocity distribution departs widely from the normal, (2) and (3) will be correspondingly in error.

32. Gages and meters

Float gage (Fig. 70) is the best instrument for measuring the elevation of a water surface. The float is a hollow box of non-corrosive metal, either spherical or cylindrical with a conical top and bottom; it is attached to a rigid vertical rod carrying an index mark which is guided along a vertical scale, or else the rod actuates an automatic recording mechanism. For accurate work the float is placed in a vertical pipe or stilling box about 1 in. greater in diameter than the float itself. Lateral motion is prevented by fins. If the pipe is capped on the bottom and small holes are made in the side to allow equalization of level, minor wave and surge action is suppressed. For large changes in level, the float is attached to a light metal graduated tape which winds about a drum provided with a suitable counterweight; the drum may actuate a pointer or a continuous recording mechanism.

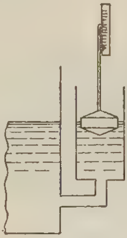

Fig. 70. Float gage.

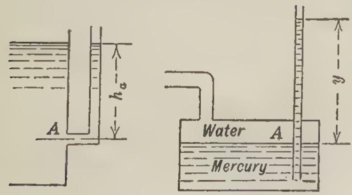
Fig 71. Hook gage.

Hook gage (Fig. 71) is a metal hook on the end of a graduated rod, equipped with vernier scale and slow motion screw. It is operated by submerging the hook and then raising it until a protuberance or pimple appears on the water surface. The hook is then depressed until the pimple just vanishes. The Vernier scale usually reads to 0.001 ft. but precise instruments read to 0.0001 ft. Under favorable conditions readings to 0.0002 ft. may be obtained.

The hook gage is usually employed for measurement of the head on a weir; for this purpose it is placed in a stilling box connected to the channel of approach some distance back of the crest. The connecting pipe is set at right angles to the current or else is perforated to eliminate velocity head. The zero reading is obtained by precise leveling. An approximate method is to read the gage when water just trickles over the weir.

Open liquid column or piezometer tube (Fig. 72) is the simplest device for measuring pressure head. Mercury is used for high pressures; water or light oil for small gas pressures. Readings should be taken tangent to the middle point of the meniscus. Tubes should be ⅜ in. or more in diameter to avoid errors due to capillarity.



$h_a = 13.57y$

Fig. 72.—Piezometer tubes.

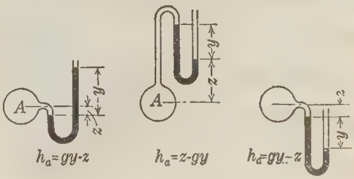


Fig. 73.—U-tubes.

Open U-tubes are used to measure small pressures both above and below atmospheric pressure. (In Fig. 73, g = specific gravity of the liquid in the tube.) Any liquid that does not react chemically with the substance gaged may be used. If applied to gas pressures, $z = 0$.

Hydraulic pressure gages are also available built on the principle of the Bourdon steam gage and of the aneroid barometer.

Differential gages (Fig. 74) measure differences in pressure only, such as the pressure loss in a pipe line due to a valve or obstruction. The mercury gage consists of a U-tube containing mercury with upper ends of the tube connected to vessels under pressure. Difference in pressure at (*A*) and (*B*) is indicated by difference in weight of a column of mercury and a column of water each y ft. in height. $h_a - h_b = 13.57yh - y = 12.57y$. An OIL GAGE is used for small differences in pressure. If the specific gravity of the oil is g, $h_a - h_b = (1 - g)y$.

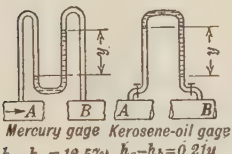

FIG. 74.—Differential gages.

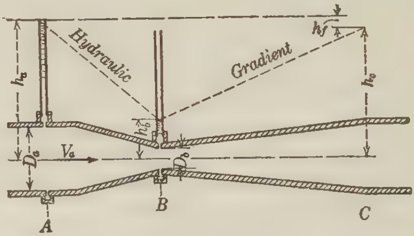

FIG. 75.—Venturi meter.

Venturi meter (Fig. 75) is an accurate and easily constructed device for measuring flow in pipes and closed conduits with any diameter. Two hollow truncated cones having the same base diameter are inserted in the pipe line; piezometer tubes are connected at the entrance and at the contracted section or throat; the pressure difference at these points is an indication of discharge.

By Bernouilli's theorem for frictionless flow in a horizontal tube, the sum of pressure head and velocity head is constant. Hence $h_a + v_a^2/2g = h_b + v_b^2/2g$. The product of velocity and cross-section area is also constant, hence if K be the ratio of large to small diameter $= D_a/D_b$, then $v_b = K^2 v_a$, and $h_a - h_b = (K^4 - 1)v_a^2/2g$ or $v_a = \sqrt{\dfrac{(h_a - h_b)2g}{K^4 - 1}}$. Introducing a constant C to allow for friction losses, discharge $q = C\dfrac{\pi D_a^2}{4} \cdot v_a$ or $q = \dfrac{C\pi D_a^2}{4\sqrt{K^4 - 1}} \cdot \sqrt{2g(h_a - h_b)}$. For any given meter this becomes $q = aH^{1/2}$ where a is a constant and H is the difference in head in feet, obtained usually by the use of a mercury differential gage. The value of C varies from 0.96 to 0.98 and the head lost in passing the meter is from 10 to 15 per cent. of the difference in head $h_a - h_b$. The ratio of pipe to throat diameter varies from 2 to 4, the larger values being used for low velocities, since in this case greater relative increase of velocity at the throat is necessary to give a reading of required sensitiveness. Care must be used that the pressure at the throat does not fall much below atmospheric; preferably it should be positive.

Venturi meters are built in standard-pipe sizes up to diameters of 60-in. They are of cast iron with bronze throat pieces and have interior surfaces highly polished. The expanding cone is about three-times the length of the contracting cone to avoid losses in impact. Piezometer connections are made to annular pressure chambers which surround the throat and entrance and are connected to the interior by a series of holes spaced equally about the circumference. Large meters are built of steel, wood stave, and reinforced concrete. Those of the CATSKILL WATER SYSTEM are of the latter type with bronze throat pieces. Diameters are 210 in. and 93 in. and capacity 650,000,000 gal. per day. Builders Iron Foundry Co. of Providence, R. I., build meters for diameters of 2 to 60 in., equipped with an automatic recording mechanism operated by floats which are supported by the mercury columns of a differential gage.

Example. Find a suitable ratio of diameters for a Venturi meter on a 24-in. pipe line discharging 16 cu. ft. per sec., if the location of the meter is 20 ft. below the hydraulic gradient.

The head at the throat is to remain positive. $v_a = 16/\pi = 5.1$. $h_a - h_b = 20$ ft. $= (K^4 - 1)v_a^2/2g$, hence $K = 2.66$. Adopting the ratio $K = 2.5$ and assuming $C = 0.97$, the discharge becomes $q = 3.95 \times H^{1/2}$.

Pitot tube is an instrument for measurement of velocity by means of the dynamic pressure of a jet. If a curved tube (Fig. 76) is placed in a jet with the plane of its orifice normal to the direction of flow, water will rise in the tube to a height h which varies directly as v^2. Theoretically the impulse of the jet should balance the head $= v^2/2g$ but experiments show that $h = Cv^2/2g$ or $v = C\sqrt{2gh}$ where C is very nearly unity; h is hence a direct measure of velocity head. The Pitot tube is used in pipes under pressure by employing two tubes, one the impact tube, and the other a tube set to record static pressure only. If h is the difference in head, $v = C\sqrt{2gh}$, and if the pressure tube has an orifice flush with the wall of the pipe C is unity.

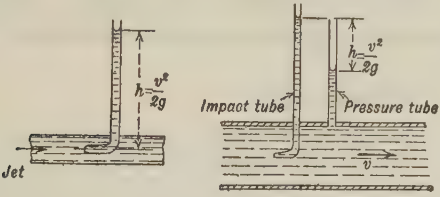

FIG. 76.—Pitot tubes.

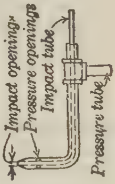

FIG. 77.

The **commercial** form of tube combines impact and pressure tubes in a single brass rod, preferably of stream-line form (Fig. 77). In such a tube the pressure openings do not record full static pressure because of disturbance produced by the presence of the tube, hence C is less than unity and depends on the relative positions of the impact and pressure openings; for Fig. 77 it varies from 0.84 to 0.88. For precise work the tube should be calibrated by moving it through still water at known velocity or by placing in a stream of known velocity.

PITOTMETER is a recent form of instrument which uses two Pitot tubes, one facing up and the other down stream. $v = 0.84\sqrt{2gh}$. Difference of head is measured by a differential gage using a mixture of gasolene and carbon tetrachloride with specific gravity 1.25 to 1.5. The instrument is equipped with a photographic recording device.

Use of Pitot tubes in pipes. Distribution of velocity in pipes is shown by Fig. 78. The velocity curve for normal distribution is a semi-ellipse; the mean velocity is 0.83 × *the center velocity*. If a straight pipe, 50-diameters or more in length, without valves or other obstructions, is obtainable, normal distribution of velocity may be assumed and discharge computed from measurement of the center velocity. For greater precision a complete traverse of the pipe cross-section is necessary. The section is divided into ten concentric circles that divide the area into tenths. The impact opening of the tube is placed on the circumference of odd-numbered circles and ten readings obtained. Since each velocity represents one-tenth area, the mean velocity is the average of the readings. Traverses should be made on two diameters at right-angles.

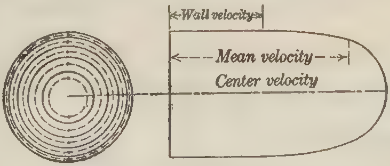

FIG. 78.—Velocity distribution in pipe, 10-point method of sectioning.

Current meter consists of a small wheel-like screw or water wheel which, when placed in a flowing stream, revolves due to the dynamic action of water, its angular speed depending on the velocity in the neighborhood of the point of immersion. The wheel is equipped with a rudder, weights, and rod or guy rope for holding at the desired position in the stream. Revolutions of the wheel are indicated by a make-and-break electric circuit and by revolution counter.

Price current meter, used by the U. S. Geologic Survey, has five conical buckets on a vertical shaft, supported by a frame which carries a rudder. The frame is pivoted to the vertical brass rod, the upper end of which has an eye for attachment of a wire or cable, and the lower end carries a lead weight, also equipped with a rudder, to hold the meter in position. In shallow water the meter is attached to a graduated brass rod without weight or rudder. Meter is equipped with revolution counter and telephone buzzer, the latter being an indication that the wheel is revolving properly. Haskell current meter has a wheel of the screw-propeller type revolving on a horizontal shaft. In other respects it is similar to the Price meter.

Calibration of a current meter. While it is possible to construct a meter for which the revolutions are proportional to the velocity, no such assumption can be made. Every instrument must be calibrated individually and at frequent intervals, especially after tightening or loosening a screw. The meter is calibrated for the desired range either by moving it through still water at the desired velocity or by holding it in a stream whose velocity is known. Rough calibration can be performed by holding the meter just below the stream surface and obtaining the velocity by surface floats. This introduces all the inaccuracies of surface-float measurements. Comparison of meter readings with those obtained from rod floats or a Pitot tube is good.

33. Water supply

Consumption of water in American cities averages about 100 gal. per day per capita; the range is from 30 to 200 gal., depending on supply, percentage metered, and nature of industries. Maximum daily consumption may exceed the mean 40 to 50 per cent.; maximum hourly consumption is determined largely by fire service and may be three times the mean daily average. In mining communities and in isolated plants consumption is determined by mill requirements; in dry or arid regions it is fixed by the amount of water available.

Rainfall and evaporation vary with the locality and vary greatly for the same locality from year to year. U. S. Weather Bureau records give the following values of mean annual rainfall over a period of nearly 30 years: Vicksburg, 53.8; New York, 43.7; Chicago, 33.4; Omaha, 30.8; Helena, 13.3; Yuma, 2.7.

Table 32. Variation in rainfall for the same locality

Locality	Yearly average	Maximum year	Minimum year	Highest 7 consecutive months	Lowest 5 consecutive months	Mean temperature
Boston	45.3	67.7	27.2	47.9	7.9	49
Croton, N. Y.	49.0	63.7	36.9	46.8	10.8	54
Philadelphia	42.6	61.2	29.7	47.7	8.1	54
Atlanta	49.2	65.0	33.0	52.7	8.1	61
Pittsburgh	35.8	50.6	25.3	38.3	6.8	53
Duluth	29.5	45.3	18.1	38.4	2.9	39
Denver	14.3	23.0	8.5	19.1	1.1	51
Phoenix	7.4	19.7	3.8	13.6	0.0	70

Table 32 shows the necessity of having records extending over a period of years.

Evaporation depends on the quantity and distribution of rainfall, temperature, barometric pressure, and nature of vegetation. For New Jersey Vermeule (*U. S. Geol. Surv. of N. J.*, 1894, *vol.* 3, *p.* 76) gives $E = F(15.50 + 0.16R)$ where E = yearly evaporation in in., $F = (0.05T - 1.48)$, T = mean yearly temperature, deg. F; R = yearly rainfall, in. In arid regions evaporation may account for the entire rainfall.

Run-off and yield. Run-off from a water-shed is the amount of water that reaches streams which drain the shed and is the difference between rainfall

and evaporation. YIELD is the collectible portion of rainfall and cannot be accurately computed until the following data are known; (1) catchment area, (2) rainfall, (3) minimum year and a series of years, (4) available storage capacity on streams, losses in evaporation and percolation, (5) measurement of actual discharge of streams. Run-off in New York and New England averages about 45 per cent. of rainfall but the percentage may vary 100 per cent for the same annual rainfall. Average yield is nearly 1,000,000 gal. per day per sq. mile. Small watersheds give a smaller yield per sq. mile than large ones. For the Pacific States Gunsky determined that the run-off may be expressed in identical percentages of precipitation expressed in inches, *i.e.*, if rainfall is 25 in., run-off is 25 per cent. or 6.25 in.; if rainfall is 10 in., run-off is 10 per cent. of 10 or 1 in.

Ground water is that part of precipitation, termed RUN-IN, which soaks into the ground. Sands and gravels permit large run-in, clay is nearly impervious. In Connecticut the run-in is 50 per cent. of the rain-fall, in New South Wales, 2 per cent. Ground water is a source of supply to wells and springs, and to streams except immediately after precipitation. For the same annual rainfall, the ratio between run-in and run-off is a factor of supreme importance in water-supply problems. A high percentage of run-in makes uniform flow in streams and gives abundant supply to wells; low run-in makes arid regions because most of the rainfall finds its way immediately to the water courses and is lost, unless excessive storage capacity is provided. Desert regions are characterized by water courses that are dry except during the period immediately after rain when the water passes off in a flood.

Wells. The horizon below which soil is saturated is called the WATER TABLE. This horizon fluctuates in height with the amount of rainfall and is, in general, parallel to, and a few feet below, the ground surface. Wells sunk below the level of the water-table are a source of supply, the yield depending on the ground water present and ease with which it can flow through the neighboring soil; this depends on the nature of the soil, typography of the country, and geologic features of the rocks. ARTESIAN WELLS are those sunk through the first impervious layer to lower water-bearing strata in which the water is under pressure. FLOW FROM WELLS can be determined only by tests and by records of existing wells in the vicinity. Long records are desirable since flow may decrease rapidly with time.

Stream flow is the usual source of water supply. Stream-flow records covering several years are necessary for dependable estimates of possible yield of a region. When records for short period only are available, rainfall records for the same period should be compared with the run-off record and with the rainfall record for a dry season. When no stream records are available, monthly rainfall records must be used, making allowance for evaporation, deep seepage, and other possible losses. To determine probable fluctuation in flow, rate of precipitation must be considered and ratio of run-in to run-off estimated from topographic features, soil, and vegetation.

Storage is impounding of water during periods of maximum flow for use during dry periods. The usual method is to build a dam in a narrow valley, or a series of such dams on tributaries wherever natural storage sites occur. The storage necessary to assure any assumed continuous draft is determined by study of stream-flow records.

In Fig. 79 the minimum draft can be raised from line A–B to line C–D by supplying storage equal to the larger shaded area representing excess of demand over supply. The height of line C–D increases with the capacity of the reservoir until it equals the mean

annual flow minus evaporation and leakage. EVAPORATION LOSSES from a reservoir are 30 to 100 in. per annum, the high figure applying to arid regions.

Example. If a hydrograph is plotted with a vertical scale of 1 = 1,000,000 gal. per day, and horizontal scale of 1 = 1 month, each square inch of area will represent 30,000,000 gal. The total storage area × 30,000,000 plus the estimated losses gives the REQUIRED STORAGE CAPACITY.

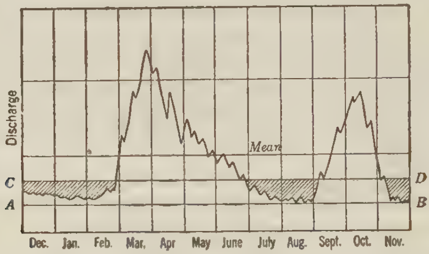

FIG. 79.

Pipe lines should have sufficient capacity to maintain a discharge of 150 per cent. average flow. The size of distribution pipes is determined by fire-service requirements. A standard stream of 250 gal. per min. through 1⅛-in. nozzle requires a pressure of 45 lb. per sq. in. at the base of the tip. Higher pressures are desirable for large buildings. Hydrants should be located so that not more than 300 or 400 ft. of hose is necessary in any one line, the pressure drop being 14 to 30 lb. per sq. in. per 100 ft., depending on the quality of hose. Two or three streams should be available for any one point. Ten standard streams are desirable for a large building.

SECTION 28

APPENDIX

Table 1. The chemical elements (based on oxygen as 16.00) (47 ACS 597 [1925]).

Element	Symbol	Atomic weight	Valence	Element	Symbol	Atomic weight	Valence
Aluminum	Al	26.97	iii	Mercury	Hg	200.61	i, ii
Antimony	Sb	121.77	iii, v	Molybdenum	Mo	96.0	iii, iv, vi
Argon	A	39.91	0	Neodymium	Nd	144.27	iii

Table 2. Composition and specific gravity of minerals

Mineral	Composition	Specific gravity	Mineral	Composition	Specific gravity
Actinolite	$Ca(Mg \cdot Fe)_3(SiO_3)_4$	3 – 3.2	Hydrozincite	$ZnCO_3 \cdot 2Zn(OH)_2$	3.58 – 3.8
Albite	$NaAl\ Si_3O_8$	2.62 – 2.65	Hypersthene	$(Fe, Mg)SiO_3$	3.4 – 3.5
Almandite	$Fe_3Al_2(SiO_4)_3$	3.9 – 4.2	Ilmenite	$FeTiO_3$	4.5 – 5.0
Amosite	$(Fe, Ca, H_2, Mn)O \cdot SiO_2$	2.2 – 2.3	Iridosmine	Ir and Os (with Rh, Pt, Ru or other metals)	19.3 – 21.12
Amphibole	See actinolite, tremolite, hornblende		Kainite	$MgSO_4 \cdot KCl + 3H_2O$	2.05 – 2.2
Analcite	$NaAlSi_2O_6 + H_2O$	2.22 – 2.29	Kaolinite	$H_4Al_2Si_2O_9$	2.6 – 2.63
Andradite	$Ca_3Fe_2(SiO_4)_3$	3.8 – 3.9	Limonite	$2Fe_2O_3 \cdot 3H_2O$	3.6 – 4.0
Anglesite	$PbSO_4$	6.12 – 6.39	Linnaeite	Co_3S_4 (with Fe or Cu)	4.8 – 5.0
Anorthite	$CaAl_2Si_2O_8$	2.74 – 2.76	Magnesite	$MgCO_3$	3.0 – 3.12
Antimony	Sb (sometimes with As, Fe or Ag)	6.5 – 6.72	Magnetite	Fe_3O_4	5.17 – 5.18
Anthophyllite	$(Mg \cdot Fe)SiO_3$	3.0 – 3.2	Malachite	$CuCO_3 \cdot Cu(OH)_2$	3.9 – 4.03
Apatite	$(Cl \cdot F)Ca_5(PO_4)_3$	3.17 – 3.23	Manganite	$Mn(OH)_3Mn_2O_3$	4.2 – 4.4
Argentite	Ag_2S	7.20 – 7.36	Marcasite	FeS_2	4.85 – 4.90
Arsenopyrite	$FeAsS$	5.9 – 6.2	Melaconite	CuO	±6.0
Atacamite	$Cu_2(OH)_3Cl$	3.75 – 3.77	Millerite	NiS	5.3 – 5.65
Azurite	$2CuCO_3 \cdot Cu(OH)_2$	3.77 – 3.83	Mispickel	See arsenopyrite.	
Barite	$BaSO_4$	4.3 – 4.6	Molybdenite	MoS_2	4.7 – 4.8
Bauxite	$Al_2O_3 \cdot 2H_2O$	2.55	Molybdite	MoO_3	4.49 – 4.5
Bentonite	$SiO_2, Al_2O_3, Fe_2O_3, CaO, MgO$	2.13	Monazite	$(Ce, La)PO_4$	4.9 – 5.3
Beryl	$Be_3Al_2(SiO_3)_6$	2.63 – 2.80	Muscovite	$H_2KAl_3(SiO_4)_3$	2.76 – 3
Biotite	$(H,K)_2(Mg,Fe)_2Al_2(SiO_4)_3$*	2.7 – 3.1	Nephelite	$NaAlSiO_4$	2.55 – 2.65
Bismite	Bi_2O_3	4.36	Niccolite	$NiAs$	7.33 – 7.67
Bismuth	Bi	9.8	Ochre	Pulverized Fe_2O_3 or $Fe_2(OH)_6Fe_2O_3$	About 4
Bismuthinite	Bi_2S_3	6.4 – 6.5	Olivine	$(Mg, Fe)_2SiO_4$	3.3
Bismutite	$(BiO)_2 \cdot CO_3 \cdot H_2O$	6.9 – 7.7	Orpiment	As_2S_3	3.4 – 3.5
Borax	$Na_2B_4O_7 \cdot 10H_2O$	1.69 – 1.72	Orthoclase	$KAlSi_3O_8$	2.47 – 2.62
Bornite	$Cu_2S \cdot CuS \cdot FeS$	4.9 5.4	Pentlandite	$(Fe, Ni)S$	4.60 – 5.0
Bournonite	$PbCuSbS_3$	5.7 – 5.9	Plagioclase	See albite and anorthite.	
Braunite	$3Mn_2O_3 \cdot MnSiO_3$	4.75 – 4.82	Platinum	Pt (alloyed with Fe, Ir, Os, etc.)	14 –19
Brochantite	$CuSO_4 \cdot 3Cu(OH)_2$	3.91	Polybasite	$(AgCu)_{16}Sb_2S_{11}$	6.0 – 6.2
Calamine	$(ZnOH)_2SiO_3$	3.4 – 3.5	Proustite	Ag_3AsS_3	5.57 – 5.64
Calaverite	$(Au \cdot Ag)Te_2$	9.04	Psilomelane	H_4MnO_5 *	3.7 – 4.7
Calcite	$CaCO_3$	2.71	Pyrargyrite	Ag_3SbS_3	5.77 – 5.86
Cassiterite	SnO_2	6.8 – 7.1	Pyrite	FeS_2	4.95 – 5.10
Cerargyrite	$AgCl$	5.55	Pyrolusite	MnO_2	4.82
Cerussite	$PbCO_3$	6.46 – 6.57	Pyromorphite	$Pb_5Cl(PO_4)_3$	6.5 – 7.1
Cervantite	Sb_2O_4	4.08 – 5.28	[illegible]	[illegible]	[illegible]
Chalcanthite	$CuSO_4 \cdot 5H_2O$	2.12 – 2.3			
Chalcedony	SiO_2	2.6 – 2.64			

Chert	SiO_2	2.6 – 2.64	[illegible]	$Ca(Mg,Fe)(SiO_3)_2$	3.2 – 3.38
Chromite	$FeCr_2O_4$	4.32 – 4.57	Pyrrhotite	$Fe_{11}S_{12}$	4.58 – 4.64
Chrysocolla	$CuSiO_3+2H_2O$	2 – 2.24	Quartz	SiO_2	2.65 – 2.66
Chrysolite	$(Mg\cdot Fe)_2SiO_4$	3.27 – 3.37	Realgar	AsS	3.56
Chrysotile	$H_4Mg_3Si_2O_9$	2.22	Rhodochrosite	$MnCO_3$	3.45 – 3.60
Cinnabar	HgS	8.0 – 8.2	Rhodonite	$MnSiO_3$	3.4 – 3.68
Clays	See kaolinite.		Ruby	See corundum	
Coal	C+H+O+N (varies)	1 – 1.8	Rutile	TiO_2	4.18 – 4.25
Cobaltite	CoAsS	6.0 – 6.3	Sapphire	See corundum.	
Colemanite	$Ca_2B_6O_{11}\cdot 5H_2O$	2.42	Scheelite	$CaWO_4$	5.9 – 6.1
Copper	Cu	8.8 – 8.9	Senarmontite	Sb_2O_3	5.3
Corundum	Al_2O_3	3.95 – 4.10	Serpentine	$H_4Mg_3Si_2O_9$	2.5 – 2.65
Covellite	CuS	4.59 – 4.64	Siderite	$FeCO_3$	3.83 – 3.88
Crocidolite	$NaFe(SiO_3)_2\cdot FeSiO_3$	3.2 – 3.3	Silver	Ag (with some Au,Cu and sometimes Pt, Sb, Bi, Hg)	10.1 –11.1
Cryolite	$3NaF\cdot AlF_6$	2.95 – 3.0	Smaltite	$CoAs_2$	6.4 – 6.6
Cuprite	Cu_2O	5.85 – 6.15	Smithsonite	$ZnCO_3$	4.30 – 4.45
Diamond	C	3.516– 3.525	Spessartite	$Mn_3Al_2(SiO_4)_3$	4.0 – 4.3
Dolomite	$Ca,MgCo_{(3)2}$	2.8 – 2.9	Sphalerite	ZnS	3.9 – 4.1
Emery	See corundum.		Spinel	$MgAl_2O_4$	3.5 – 4.1
Enargite	Cu_3AsS_4	4.43 – 4.45	Spodumene	$LiAl(SiO_3)_2$	3.13 – 3.20
Epidote	$Ca_2(AlOH)Al_2(SiO_4)_3$	3.25 – 3.5	Stannite	Cu_2FeSnS_4	4.5 – 4.52
Erythrite	$Co_3As_2O_8\cdot 8H_2O$	2.95	Stephanite	Ag_5SbS_4	6.2 – 6.3
Ferberite	See wolframite.		Stibnite	Sb_2S_3	4.52 – 4.62
Fluorite	CaF_2	3.01 – 3.25	Sulphur	S	2.07 – 2.09
Franklinite	$(Zn,Mn)Fe_2O_4$	5.07 – 5.22	Sylvanite	$(Au,Ag)Te_2$	7.9 – 8.3
Galena	PbS	7.4 – 7.6	Talc	$H_2Mg_3(SiO_3)_4$	2.7 – 2.8
Garnet	See various forms (p. 115).		Tennantite	$Cu_8As_2S_7$	4.37 – 4.49
Garnierite	$H_2(Ni\cdot Mg)SiO_4+H_2O$	2.27 – 2.8	Tenorite	CuO	5.82 – 6.25
Gibbsite	$Al(OH)_3$	2.3 – 2.4	Tetrahedrite	$Cu_8Sb_2S_7$	4.4 – 5.1
Gold	Au (with Ag and sometimes Cu or Fe)	15.6–19.3	Titanite	$CaSiTiO_5$	3.4 – 3.56
Graphite	C	2.09 – 2.23 (2.9, impure)	Topaz	$Al_2F_2SiO_4$	3.4 – 3.6
			Tourmaline	$R_9Al_3B_2(OH)_2Si_4O_{19}$ †	2.98 – 3.20
Grossularite	$Ca_3Al_2(SiO_4)_3$	3.42 – 3.72	Tremolite	$CaMg_3(SiO_3)_4$	2.9 – 3.1
Gypsum	$CaSO_4+2H_2O$	2.31 – 2.33	Uvarovite	$Ca_3Cr_2(SiO_4)_3$	3.41 – 3.52
Halite	NaCl	2.4 – 2.6	Valentinite	Sb_2O_3	5.57
Halloysite	$H_4Al_2O_3\cdot 2SiO_2+H_2O$*	2.0 – 2.2	Wad	See psilomelane	3.0 – 4.26
Hematite	Fe_2O_3	4.9 – 5.3	Willemite	Zn_2SiO_4	3.89 – 4.18
Hessite	Ag_2Te	8.31 – 8.45	Witherite	$BaCO_3$	4.27 – 4.35
Hornblende	$mCa(MgFe)_3(SiO_3)_4 + n(Al,Fe)(F,OH)SiO_3$	±3.2	Wolframite	$(Fe,Mn)WO_4$	7.2 – 7.5
			Wulfenite	$PbMoO_4$	6.7 – 7.0
Hübnerite	$MnWO_4$	6.8	Zincite	ZnO	5.43 – 5.7
			Zircon	$ZrSiO_4$	4.68 – 4.70

* Approximate. † R = Fe, Mg and the alkalies.
